OF THE

AMERICAN SOCIETY

OF

CIVIL ENGINEERS

(INSTITUTED 1852)

TRANSPORTATION LIBRARY
UNIVERSITY OF MICHIGAN

VOL. LXXXIII

1919-1920

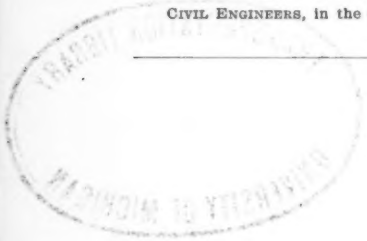
Edited by the Secretary, under the direction of the Committee on Publications.
Reprints from this publication, which is copyrighted, may be made on condition that the full title of Paper, name of Author, and page reference are given.

NEW YORK

PUBLISHED BY THE SOCIETY

1921

Entered according to Act of Congress, in the year 1921, by the AMERICAN SOCIETY OF CIVIL ENGINEERS, in the Office of the Librarian of Congress at Washington.



NOTE.—This Society is not responsible for any statement made or opinion expressed in its publications.

CONTENTS

PAPERS

No.		PAGE
1426	**THE ECONOMICS OF STEEL ARCH BRIDGES.**	
	By **J. A. L. Waddell**	1
	Discussion:	
	By PAUL A. BLACKWELL	42
	T. KENNARD THOMSON	43
	CHARLES EVAN FOWLER	47
	W. B. FARR	66
	HORATIO P. VAN CLEVE	69
	HENRY S. JACOBY	70
	H. S. SALES	73
	DAVID A. MOLITOR	79
	EDWARD W. STONEY	85
	F. H. FRANKLAND	86
	J. A. L. WADDELL	90
1427	**VERIFICATION OF THE BAZIN WEIR FORMULA BY HYDRO-CHEMICAL GAUGINGS.**	
	By **Floyd A. Nagler**	105
	Discussion:	
	By CLEMENS HERSCHEL	157
	DAVID A. MOLITOR	164
	FREDERIC P. STEARNS	169
	B. F. GROAT	187
	FLOYD A. NAGLER	188
1428	**DETERMINATION OF THE DUTY OF WATER BY ANALYTICAL EXPERIMENT.**	
	By **W. C. Hammatt**	200
	Discussion:	
	By J. C. VAN REIGERSBERG VERSLUYS	251
	W. L. ROCKWELL	251
	J. C. STEVENS	252
	S. T. HARDING	263
	W. C. HAMMATT	267
1429	**CEMENT JOINTS FOR CAST-IRON WATER MAINS.**	
	By **Clark H. Shaw**	277
	Discussion:	
	By HARRY Y. CARSON	288
	F. M. RANDLETT	292
	WALTER PEARL	296
	H. G. MOULTON	299
	H. B. LYNCH	301
	EDWARD R. BOWEN	302
	GEORGE W. PRACY	303

No.		PAGE
1430	**CONSTRUCTION METHODS USED IN BUILDING THE LOWER RESERVOIR DAM OF THE BALMORHEA PROJECT.**	
	By **Vernon L. Sullivan**	305
	Discussion:	
	By VERNON L. SULLIVAN	315
1431	**IMPROVING ARCH ACTION IN ARCH DAMS.**	
	By **L. R. Jorgensen**	316
	Discussion:	
	By W. P. CREAGER	332
	S. H. WOODARD	333
	W. H. R. NIMMO	333
	L. R. JORGENSEN	335
1432	**SEWAGE AND WASTES DISPOSAL FOR THE UNITED STATES ARMY.**	
	By **Leonard S. Doten**	337
	Discussion:	
	By LEONARD METCALF	353
	NICHOLAS S. HILL, JR	355
	ALMON L. FALES	357
	KENNETH ALLEN	359
	G. BERTRAM KERSHAW	361
	EDMUND B. BESSELIEVRE	364
	GEORGE T. HAMMOND	369
	A. L. SHERMAN	380
	J. F. BROWN	381
	LYNN E. PERRY	386
	LEONARD S. DOTEN	389
1433	**ADDRESS AT THE ANNUAL MEETING, JANUARY 15th, 1919.**	
	By **Arthur N. Talbot**	404
1434	**THE PROPOSED NEW YORK AND NEW JERSEY VEHICULAR TUNNEL: AN INFORMAL DISCUSSION.**	
	By EDWARD A. BYRNE	427
	JOHN F. O'ROURKE	443
	PAUL G. BROWN	452
	J. V. DAVIES	454
	JAMES FORGIE	456
	W. C. PARMLEY	459
	T. KENNARD THOMSON	468
	F. LAVIS	473
	CALVIN TOMKINS	474
	AMOS SCHAEFFER	476

Paper No. 1426

THE ECONOMICS OF STEEL ARCH BRIDGES*

By J. A. L. Waddell, M. Am. Soc. C. E.

With Discussion by Messrs. Paul A. Blackwell, T. Kennard Thomson, Charles Evan Fowler, W. B. Farr, Horatio P. Van Cleve, Henry S. Jacoby, H. S. Sales, David A. Molitor, Edward W. Stoney, F. H. Frankland, and J. A. L. Waddell.

Synopsis.

Up to the present time, nothing at all certain has been known concerning the economics of steel arch bridges, the weights of metal required to build them, or how they compare in cost with corresponding steel truss bridges.

The objects of this paper and its anticipated discussions are to settle finally every important economic question that can arise in the designing of steel arches; to give formulas and diagrams for determining, with a fair amount of accuracy, the weights of metal in both arch bridges as a whole and the arches themselves; and to indicate the relations between the weights and costs of arch bridges in comparison with those of corresponding truss bridges.

There are eight economic problems set for solution, and all of them have been solved—the first two by using certain formulas given in the writer's new book, "Bridge Engineering", and the other six by a large number of special arch designs and the resulting estimates of weights of metal. Incidentally, during the investigation, there have arisen and have been solved a few minor questions which may properly

* Presented at the meeting of May 1st, 1918.

be termed side issues. The computations have been made for both railway and highway arch bridges; and the weights of metal are plotted for both carbon-steel and nickel-steel structures. Several diagrams are given to show the percentage effects of weight increase due to departure from economic conditions.

The need for the special knowledge concerning arch bridges presented in this paper has been recognized during the last three decades by American structural steel engineers; but the authors of books on bridges (the writer included) have hitherto avoided the issue because of the immense amount of work involved in the solution of the various problems. The writer has tried of late years on several occasions to persuade some of his brother engineers to undertake the task; but, not meeting with any success, he finally decided to do the work himself. The results of his efforts are herewith presented to the members of the Society with a most earnest request for a thorough discussion, particularly by those who specialize in bridgework.*

Concerning the economics of steel arches, very little, indeed, is known, the reasons being that comparatively few such structures have been built in America, and that the subject of economics in bridge design is a study to which, generally speaking, but slight attention has been paid until late years. Occasionally, an American bridge engineer builds a steel-arch structure; but usually simple-truss spans are adopted because their approximate weights and their economics are on record. The writer is of the opinion that if more were known generally concerning the weights of metal in steel-arch structures, their economic functions, and their comparative economy in respect to the corresponding simple-truss structures, the esthetic type would be adopted more frequently, in spite of the greater labor it involves in both designing and construction. An arch is almost always a handsomer structure than an ordinary truss bridge; and the time has

* As it would be out of the question to publish the great mass of graphic calculations of stresses, diagrams of stresses and sections, tabulated estimates of weights of metal, and other computations which were prepared specially for this paper, copies of them are filed in the Engineering Societies Library, and as the original dimensions of the paper have been reduced in the interest of economy of publication, the memoir as first written will also be so filed.

The writer desired to quote three pages from the chapter relating to Arch Bridges from his book "Bridge Engineering", giving ten equations which form the basis of the solution of the first two problems discussed, and an explanation of how they were established, but this was prevented by the requirements of the Publication Committee. It will be necessary, therefore, for the reader to refer to the author's book in order to comprehend the *modus operandi* of solving the said two problems.

arrived for all American engineers to pay proper attention to the important feature of esthetics in the preparation of designs.

The economic problems concerning the design of steel arch bridges which still require solution are:

First.—The economic ratio of rise to span length;

Second.—The economic depths for the ribs;

Third.—The economic location for the crown-hinge in three-hinged, spandrel-braced arches;

Fourth.—The ratios of weights of metal required for the solid-rib, the braced-rib, and the spandrel-braced types;

Fifth.—The ratios of weights of metal required for the hingeless, the two-hinged, and the three-hinged types;

Sixth.—The economics involved by making arches three-hinged for the dead load and two-hinged for the live load;

Seventh.—The economy of the cantilever arch with suspended end spans, as compared with an ordinary arch and two flanking simple-truss spans; and

Eighth.—The ratios of weights of metal required for certain portions of arch bridges as compared with the corresponding portions of simple-truss bridges of the same span and the same live-load carrying capacity.

Problem No. 1.

Up to the present time, no reliable information has been available concerning the economic ratios of rise to span length, a few computers recognizing that it lies between the limits of 15 and 30%; but no systematic investigation of the question, as far as the writer knows, has ever been made.

However, by the use of ten equations* for three-hinged arches, the weights of metal for both the solid-rib and the braced-rib types of various span lengths, and having any ratio of rise to span, any depth of rib, and any live load or dead load, can be found readily and with considerable accuracy. The formulas given by these equations are based on the writer's specifications for designing†; which specifications, it is generally acknowledged, are substantially in accordance with the best American bridge engineering practice. From these equations, by

* Given in Chapter XXVI of the writer's "Bridge Engineering."
† "Bridge Engineering", Chapter LXXVIII.

the substitution of certain assumed values, can be found both the economic ratios of rise to span length and the economic depths of arch ribs.

In order to cover effectively the ordinary range of span lengths for arch designing, it was necessary to compute for three lengths, *viz.*, 200, 500, and 800 ft.; and, in order to include all ordinary structures, it was decided to determine the economic functions for both steam-railway bridges and combined highway and electric-railway bridges. For steam-railway bridges, double-track structures to carry Class-60 live load were adopted; and for combined highway and electric-railway bridges there was chosen a deck, 60 ft. wide from out to out, having at the middle a double-track electric railway, on each side of the latter an 11-ft. clear space for vehicles, and on the outside of each roadway an 8-ft. sidewalk, the entire roadway, including the track space, being paved with creosoted blocks resting on a reinforced concrete base, and the sidewalks being of reinforced concrete slabs.

The work involved in the investigation was, of necessity, reduced to a minimum, being great enough, in all conscience, as it was; hence solid-rib arches were computed for spans of only 200 ft., because structures of that type of longer span would be uneconomical. In some cases, owing to the cut-and-try method which had to be adopted, many assumptions of ratios of rise to span were tested; but, in order to save space, the unnecessary results have not been recorded, three only for each case serving the purpose of determining the minimum.*

In finding the weights of metal, it was necessary first to assume the depths of the arch ribs, and afterward to test them for economy; but, fortunately, in every case the first guess was almost exactly correct. These checks on the economic depths of arch ribs are discussed hereinafter.

In computing the economics of arches, it is not sufficient to ascertain merely the weights of metal in the arch ribs, for it is necessary to take into consideration also the weights of metal in the superimposed columns and the vertical sway bracing between them; and in comparing the weights of arches with those of the corresponding simple trusses, the former must be increased by the weights of such columns and their vertical sway bracing. In general, it may be assumed that the weight of the entire lateral system in a simple-truss bridge will

* See manuscript on file in the Engineering Societies Library.

offset that in the bracing of the floor system, plus that of the rib flanges of the corresponding arch structure, plus that of the other diagonals between the arch ribs. The error involved in this assumption is so small that it will not affect the correctness of the comparisons made in this investigation.

The problem of determining the economic ratio of rise to span is not as simple as it might appear at first thought; for it is a compound one, being dependent on the conditions precedent. These may be divided into four cases, *viz:*

First.—When the rocky sides of the chasm to be spanned are practically vertical, with the grade line about tangent to the crown of the top chord of the arch. In this case, as previously indicated, the weight of the superimposed columns and their bracing must be considered with that of the arch rib in determining the economic rise.

Second.—In the case of a half-through structure, where the variations in the sum of the weights of hangers and columns are comparatively slight for changes in rise, and where, consequently, the economics are dependent mainly on the weight of the arch rib alone.

Third.—When the grade line is far above the crown of the arch, and, consequently, the greater the rise the less the weight of the superimposed columns and their bracing. This is just the opposite condition to that of the first case, because, in that one, the greater the rise the greater is the average length of the spandrel columns.

Fourth.—When the chasm is decidedly **V**-shaped. In this case the grade line may be either tangent to, or well above, the crown of the top chord.

These four cases have been considered separately.*

Case No. 1.—From Table 1 it may be concluded that for braced-rib arches the economic ratio of rise to span for all spans between 200 and 800 ft. may be taken at 0.225, without making any appreciable error. The calculations, however, show that within the limits of 0.2 and 0.25 there is very little variation of arch weight. In many cases one cannot exercise much choice in the selection of the rise for an arch, because the profile of the crossing and the adopted grade

* In the original memoir are given the designing data and the tabulated results of substitution in formulas for seven cases of both railway and highway bridges and covering both solid-rib, and braced-rib arches, also a few notes concerning certain short cuts that were used in the computation. Each table contains three records, the middle one indicating the economic ratio of rise to span, because it records the minimum weight of metal, in pounds per linear foot per side.

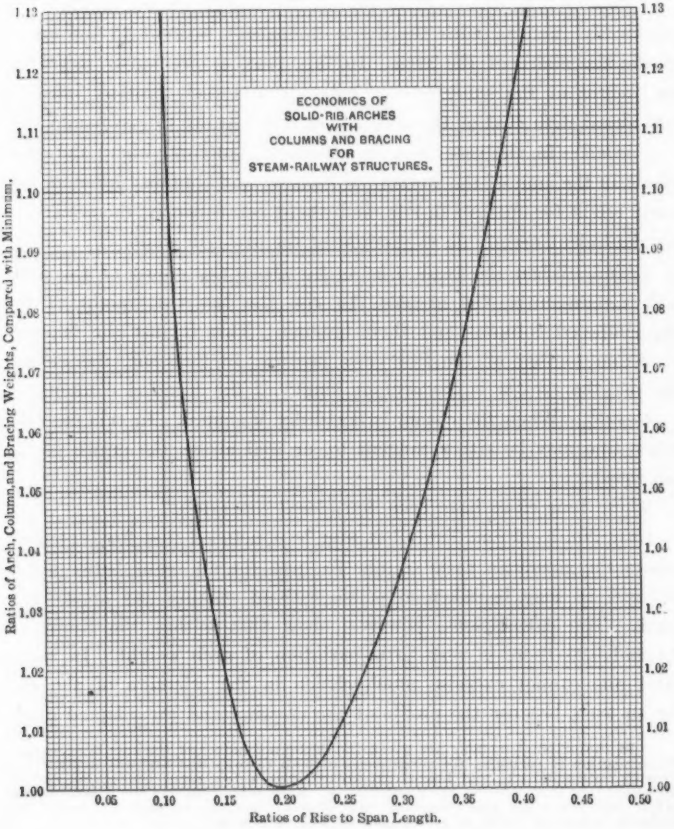

FIG. 1.

line of floor will be the governing factors. Under such conditions one should use a ratio as near to the economic one as practicable. Fortunately, as far as the matter of esthetics is concerned, such ratio is not a vital feature; and the calculations show, as just indicated,

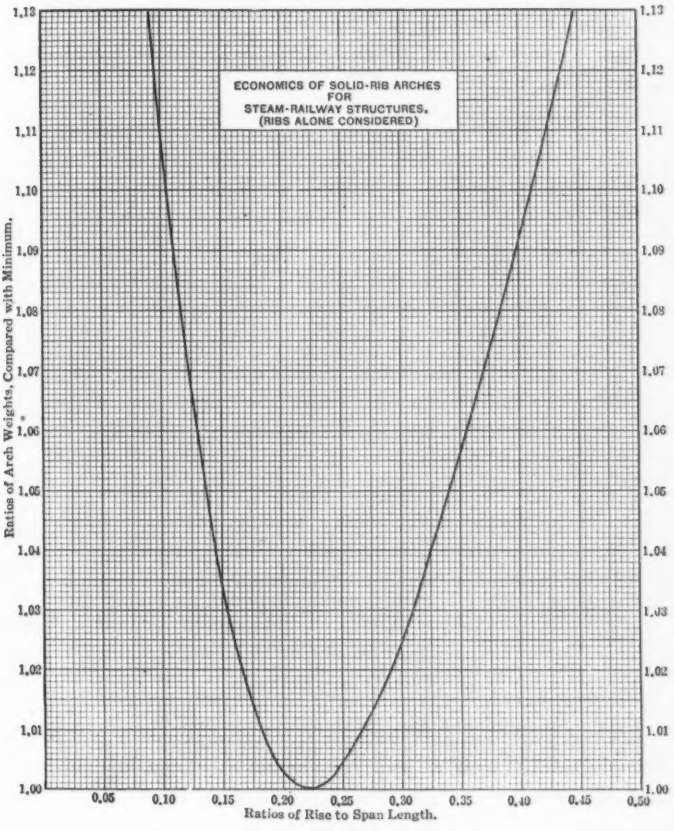

FIG. 2.

that it can be modified considerably without greatly augmenting the total cost of the structure.

For solid-rib arches, the most economic ratio of rise to span may be taken as 0.2, and the ordinary range as from 0.175 to 0.225. In order to show graphically the economics of solid-rib arch bridges,

Figs. 1 and 2 have been prepared, the former being applicable when the superimposed columns and their bracing are considered, and the latter when only the ribs themselves are under discussion. The abscissas represent the ratios of rise to span length, and the ordinates the corresponding percentages of metal required, the percentage for the minimum weight being one hundred.

Figs. 3 and 4 present the same data for braced-rib arches as are shown in Figs. 1 and 2 for solid-rib arches.

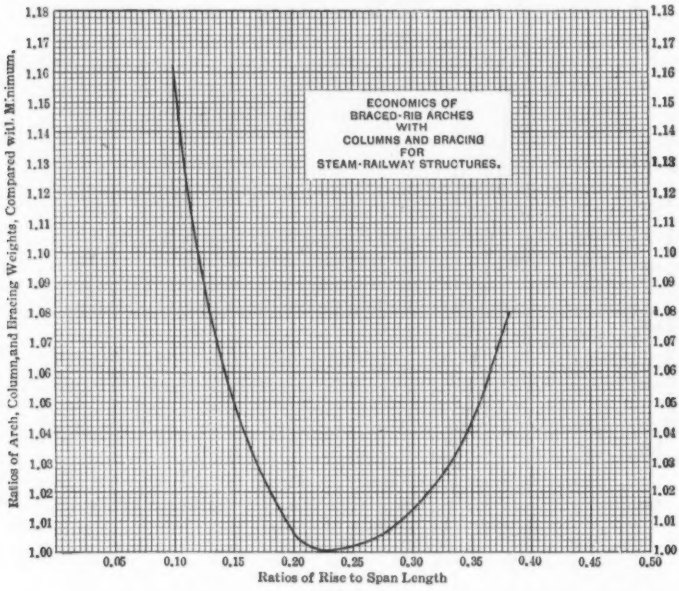

FIG. 3.

Another deduction that may be made from Table 1 is that the economic ratio of rise to span is independent of the kind of traffic which the structure carries; and the calculations have indicated that it is independent also of the size of the loading.

Case No. 2.—A systematic extension of the economic calculations for the 200-ft. and the 500-ft. spans showed that, for the solid-web type, the economic ratio of rise to span (when merely the weight of the arch itself is considered) is 0.225; and for the braced-rib type it is 0.3. A variation of 0.025 in either direction, however, does not greatly increase the weight of metal.

Case No. 3.—When the grade line is well above the crown of the arch, as shown in Fig 5, it is evident that the greater the rise, the less will be the average length of the superimposed columns and

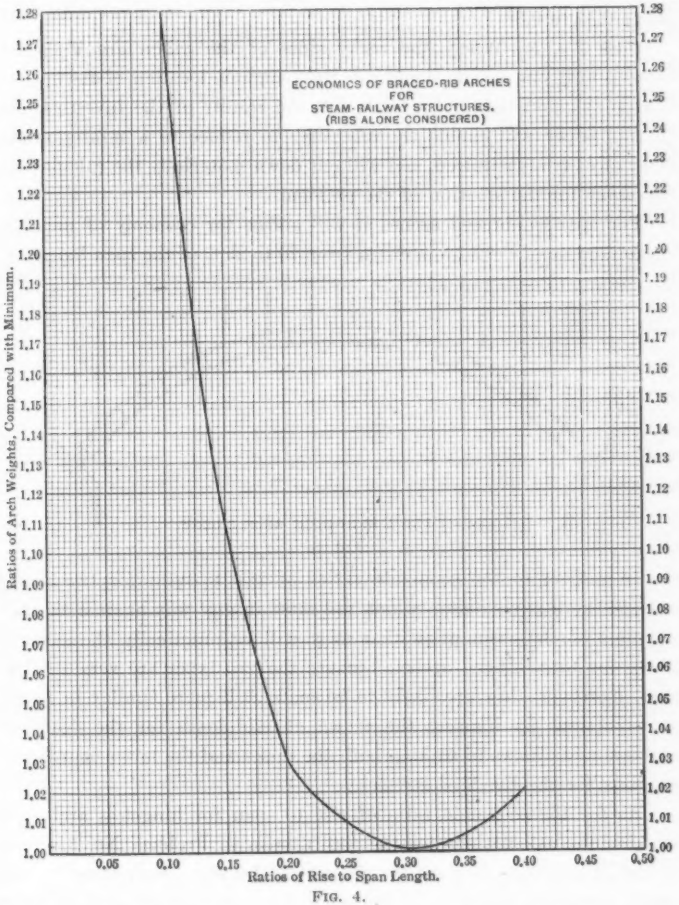

FIG. 4.

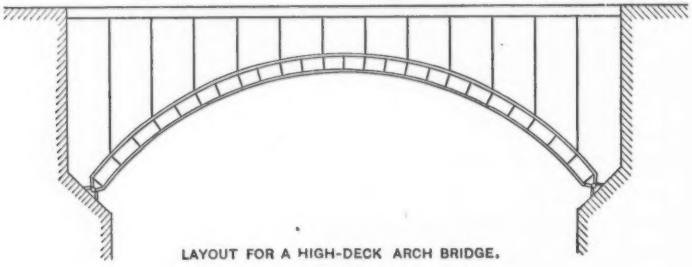
bracing—also that the greater the vertical distance between crown and grade the greater the saving in metal weight per foot of vertical reduction in height of columns. This last consideration, though, is of minor importance, and would affect very slightly, indeed, the

economic ratio of rise to span. For the solid-rib type, that ratio for high-decked arches (those where the grade is well above the crown) will vary from about 0.25 to 0.28, and for the braced-rib type from about 0.35 to 0.38.

Case No. 4.—Where the rocky sides of the cañon are V-shaped, there is only one way to determine the economic location of the springing points, and that is by trial; but the results of the investigations in this paper will enable the computer to reduce to a minimum the number of trials required, and will cut down materially the calculations necessary for the solution of the problem.

For spandrel-braced arches it will suffice for economy of metal to make the rise of the bottom chord from 20 to 25% of the span length.



LAYOUT FOR A HIGH-DECK ARCH BRIDGE.

FIG. 5.

In respect to the economic ratios of rise to span for two-hinged arches, there is no reason which militates in any way against the correctness of the assumption that they will be practically the same as those for three-hinged arches, because the two types are very similar; and, moreover, they are likely to be made still more similar in future constructions by hinging the crown at mid-depth for the dead-load stresses and afterward making both the upper and the lower chords continuous for the live-load stresses.

As for the economic ratio of rise to span for hingeless arches, in making the calculations for the 500-ft. span in Problem No. 5, it was assumed to be the same as for three-hinged arches, computing in both cases along the mid-line of the rib; but some special supplementary calculations, involving an entirely new layout and design, showed that it is somewhat greater. It may be taken as 0.28 when the grade line is about tangent to the crown of the upper chord, as 0.33 for half-through arches, and as 0.38 for high-deck structures.

PROBLEM No. 2.

As far as solid-rib arches are concerned, the question of the economic depth of the rib does not arise; because that dimension should always be made as great as a proper consideration of the section for resisting compression will permit. The member acts as both a beam and a strut; hence, if the webs are made thin and of economic depth for the bending, they will not be thick enough to comply with the rules governing the proportioning of built compression members. It is true that rigid adherence to these rules is not always necessary in arch designing, but they should never be transgressed to any great extent.

For braced-rib arches, however, it is practicable to use the economic rib depth. Up to the present time, no rule for determining this has been given. Fortunately, No. 8 of the before mentioned ten equations offers a means for solving the problem. The area of the chords,

$$A_c = \frac{T + \frac{2\,M}{d}}{p_c},$$

is divided into two parts, *viz.*, $A_t = \frac{T}{p_c}$, due to direct thrust, and $A_m = \frac{2\,M}{d\,p_c}$, due to bending from the live load only, provided that the center line of the rib is properly located; in which case the area for the web, $A_w = \frac{2\,S}{p_w}$, is also due to live load only. On that basis the partial weight of the chords, A_m, should equal the weight of the web, in order to obtain the greatest possible economy of metal. After determining the values of A_m and A_w, if they are found to be unequal, the economic depth, d', can be obtained thus:

$$A'_m = A_m \times \frac{d}{d'},$$

$$\text{and } A'_w = A_w \times \frac{d'}{d}.$$

Equating these makes $A_m \frac{d}{d'} = A_w \frac{d'}{d}$, or $d' = d\sqrt{\frac{A_m}{A_w}}$

Replacing A_m and A_w by their values gives:

$$d' = d\sqrt{\frac{\frac{2\,M}{d\,p_c}}{\frac{2\,S}{p_w}}} = d\sqrt{\frac{M\,p_w}{S\,d\,p_c}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

After making the calculations to determine the economic ratio of rise to span for each case, the assumed economic rib depth was checked by Equation (1), the results being as shown in Table 2.

TABLE 2.

Span, in feet.	Assumed depth, in feet.	Economic depth, in feet.	Ratio of economic depth to span.
200	16	15.48	0.0774
500	40	38.65	0.0773
800	60	60.24	0.0753

It is evident from Table 2 that the economic depths of braced-rib arches vary from about 7.5 to 7.75% of the span; but no mistake of any importance would be made if they were taken as 7.5% for three-hinged arches of all span lengths. There is no reason for deeming that the economic depth is any different in the case of two-hinged arches; and in hingeless arches it is probable that the economic average depth will be about the same. In spandrel-braced arches, it will suffice to make the arch depth at mid-span equal to from 6 to 8% of the span length; but here esthetics—not economics—should govern.

In two-hinged arches of very great span length, such as the famous Hell Gate Arch Bridge, it is proper to consider the economics involved by varying the arch depth approximately in proportion to the size of the bending moment. Such treatment would place the greatest depth at the haunches or quarter points; and in certain cases of long spans this might be permissible, from the esthetic standpoint, but generally it is not. Crescent-shaped, two-hinged arches are economic in the feature of reducing the rib depth gradually in the outer quarters of the span; but to the untrained eye they suggest an element of weakness. Of course, the real strength is dependent solely on whether sufficient sectional areas of members, with the metal properly disposed, have been provided; but the element of stiffness is certainly not improved by making the ribs shallow—and rigidity is often just as essential as mere strength. Making the rib depth proportional to the bending moment involves uniformity in the chord sections; but this is no important desideratum. In designing arch bridges, esthetics and rigidity should never be sacrificed for the sake of economy in weight of metal, nor for convenience in manufacture.

The before-mentioned tests prove that the economic rib depth is the same for both railway and highway structures, and that it is almost entirely independent of the size of the live load.

In order to indicate the effect on the total weight of metal by varying from the economic rib depth, take the case of the 800-ft. span, in which the assumed depth of 60 ft. was almost exactly correct, and test the increase for other depths. In the railroad structure, taking the values of A_m and A_w equal to 177 sq. in. and assuming various depths, we have the results given in Table 3, from which

TABLE 3.

Assumed depth, in feet.	Ratio of assumed depth to economic depth.	$A_m + A_w$, in square inches.	Corresponding increased percentage of total weight of ribs.
30	0.50	442.5	13.0
35	0.58	406.7	7.7
40	0.67	383.5	4.3
45	0.75	368.7	2.2
50	0.83	359.9	0.9
55	0.92	355.3	0.2
60	1.00	354.0	0.0
65	1.08	355.1	0.2
70	1.17	358.2	0.6
75	1.25	362.9	1.3
80	1.33	368.7	2.2
85	1.42	375.7	3.2
90	1.50	383.5	4.3

it is evident that, for the particular span under consideration, a material variation from the economic depth of rib may be made without greatly increasing the weight of metal in the arch. Any variation that is likely to be adopted will be a reduction; because, generally, the appearance of the arch is improved by making its rib depth smaller than the economic one. The reason the percentages in the table do not increase faster with the variation in depth from the most economic is that, for this span, the area of chord section affected by the bending moment is only about one-third of the total area. The writer recognizes that this demonstration is open to criticism, because he has neglected the increase in chord sections due to the augmented dead load; but the amount thereof is immaterial.

The results in Table 3 are shown by diagram in Fig. 6. Although it is true that this diagram was prepared for spans of 800 ft., it can be used, with sufficient accuracy for all practical purposes, in the case of arches of other span lengths, its main purpose being to show about

how far in any case it is advisable to depart from the economic rib depth, which, as previously indicated, is 7.5% of the span length.

It might be well to point out that the shorter the span the greater will be the percentage of increase in weight of arch rib, for the same ratio of actual to economic rib depth. For instance, in Table 3, which

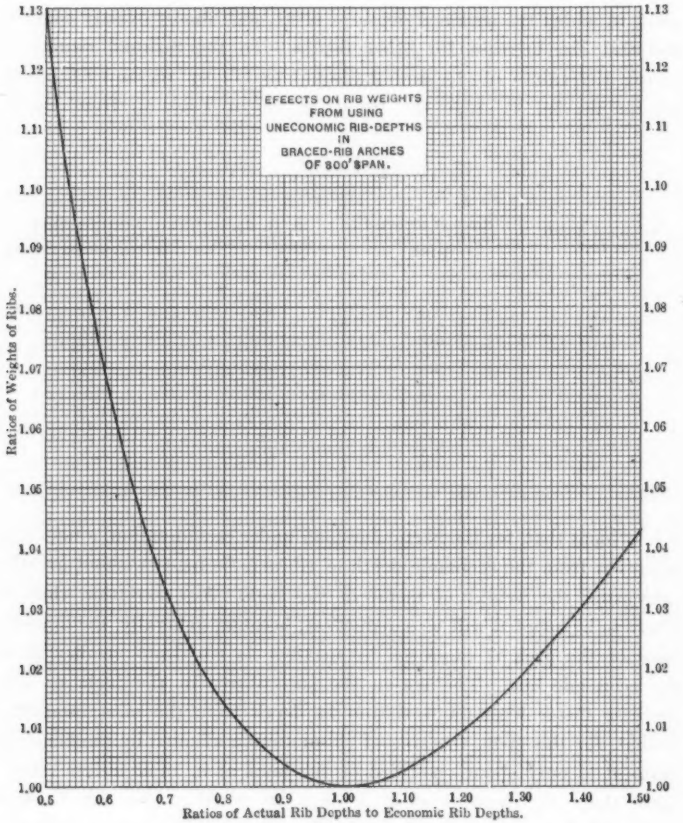


FIG. 6.

is for an 800-ft. span, if the depth is made 75% of the economic one, the increase in weight of rib metal will be 2.2%; but, in a 500-ft. span, it would be about 2.4%, and about 2.8% in a 200-ft. span. These figures endorse the statement previously made that it is proper to use the diagram, Fig. 6, for all span lengths.

PROBLEM NO. 3.

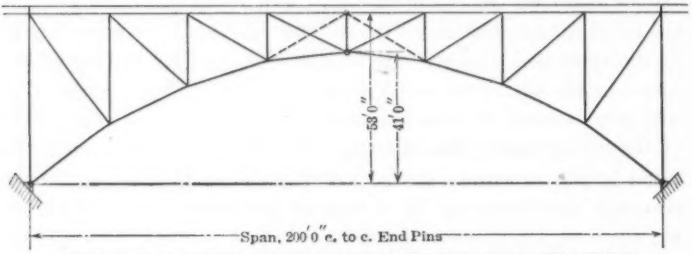
Strictly speaking, a spandrel-braced arch bridge is a structure in which the dead-load thrusts and the full live-load thrusts are carried directly by the bottom chords of the arches, the top chords and the web members serving only to brace the bottom chords under unsymmetrical or partial loading. The spandrel members thus have only a stiffening function to perform, similar to that of the stiffening truss of a suspension bridge—hence the name, "Spandrel-Braced Arch". In accordance with that definition, the crown-hinge in a spandrel-braced arch should, from the theoretical point of view, be in the bottom chord, thus obviating the necessity of the stresses from dead load and full live load traveling through the spandrel members. The simplest and most direct stress path, *viz.*, through the bottom chord, apparently should afford the maximum economy; but, in light bridges, some of the top-chord members may have sections unavoidably large in respect to the theoretical requirements; and in that case the placing of the hinge in the top chord would tend to utilize a certain quantity of idle metal, and, at the same time, reduce the sectional area of a portion of the bottom chord, thus effecting a saving in the total quantity of metal in the structure. In the writer's opinion, this is a legitimate economic expedient; but he is opposed to putting the crown-hinge anywhere except at mid-depth of rib in the case of both solid-rib and braced-rib arches. The object of this last suggested arrangement is to divide the thrust equally between the upper and lower chords of the rib; then, by keeping the center line of the latter as nearly as may be on the arc of a parabola, the chord stresses due to direct thrust will tend to divide themselves equally between the two chords, provided, of course, that the dead load is uniformly distributed. The curve of the bottom chord of a spandrel-braced arch, passing through the three hinges, should be a parabola, if the dead load is practically uniform across the span; otherwise, this curve should correspond to the equilibrium polygon for

$$\text{D. L.} + \tfrac{1}{2}\ (\text{L. L.})$$

covering the whole span.

In order to settle this question of the best location of the crown-hinge in the spandrel-braced arch, and at the same time to compare the weights of spandrel-braced arches with those of the corresponding solid-rib and braced-rib arches, two designs have been made for a

200-ft. span, spandrel-braced, steam railway, arch bridge, having the same vertical distance between top-chord and springing points as in the other two cases, as well as the same panel length and the same live load. For the purpose of avoiding the adoption of an uneconomic ratio of rise to span length, the arch depth was reduced to 12 ft. at the crown. With a depth of 53 ft. at the springing points, this provides a neat layout, as shown in Fig. 7; and the ratio of rise to span, measured on the bottom chord, is 0.2, which is about the inferior limit of the economic range. With the crown-hinge in the top chord, the ratio of rise to span length is 0.265, which is a trifle above the superior limit of the said range. These two layouts give a fair comparison between the structure with the bottom-chord crown-hinge and that with the top-chord crown-hinge. In this case there is no need of



LAYOUT FOR A 200-FOOT, SPANDREL-BRACED, STEAM RAILWAY, ARCH BRIDGE.
(Dotted lines represent reversed position of the diagonals at the crown when the hinge is located in the top chord.)

FIG. 7.

including the weights of the lateral systems in the comparison, as they are the same for each structure. The results of the calculations show that the weights of metal per linear foot of span per side (for arches only) are 1 182 lb. with the hinge in the bottom chord and 1 146 lb. with the hinge in the top chord. Contrary to what might be anticipated from purely theoretical considerations, placing the hinge in the top chord produces a less total weight of arch metal than placing it in the bottom chord, the difference in this case being about 3 per cent. A study of the two diagrams of stresses and sections shows that this result is due primarily to the effect of reversing stresses. Had the latter been ignored, the economics would have been reversed, and the difference would then have been 5% in favor of the location in the bottom chord. The provision for reversal of stresses is respon-

sible for 10% of the total weight of metal with the hinge in the bottom chord, and for only 2% thereof with the hinge in the top chord.

In the solution of Problem No. 7, it became necessary to compute the weight of metal for a 500-ft., spandrel-braced, three-hinged arch; and advantage was taken of this to find the effect on the total weight of arch metal by placing the crown-hinge first in the top chord and then in the bottom chord. The ratio of weights of metal proved to be 1.04, the economics being in favor of the higher hinge.

These results agree in kind, but not in amount, with the subsequently mentioned findings of Merriman and Jacoby in their investigation of the economics of the Niagara Arch Bridge. It may be finally concluded, therefore, that in spandrel-braced, three-hinged arches the economic location of the crown-hinge is in the upper chord.

Problem No. 4.

In determining the ratios of weights of metal required for the solid-rib, the braced-rib, and the spandrel-braced types, it was thought at first that it would suffice to test for the 200-ft. span only, and to make the assumption that what holds true for that length will hold also with sufficient exactness for all other span lengths; but, later, it was necessary to compare some longer spans. The weights of the arches with the superimposed columns and their bracing have already been determined for the solid-rib and the braced-rib types; and two spandrel-braced, steam-railway, arch bridges, of the same live-load carrying capacity and having the same vertical distance between grade and springing points, have been designed, and their weights of metal have been computed. From these weights and by using certain data in the writer's latest published work on bridges, there have been computed the weights of metal per linear foot of span per side in the 200-ft. arches and the corresponding lateral system, *viz.*, 1 146 and 204 lb., respectively, making a total of 1 350 lb.

From this and other weights previously found we have the data in Table 4.

TABLE 4.

Type of arch structure (200-ft. span.)	Total weight of metal, in pounds per linear foot per side, for ribs and lateral system.
Solid-rib	1 950
Braced-rib	1 490
Spandrel braced	1 350

Had the weight of metal in the floor system and that on piers been included in each case, we should have had the weights given in Table 5.

TABLE 5.

Type of arch structure (200-ft. span.)	Total weight of metal, in pounds per linear foot of structure, including metal on piers.
Solid-rib	5 500
Braced-rib	4 580
Spandrel-braced	4 330

From Table 5 it is evident that, even with a somewhat lower pound price of metal for plate-girder structures, the braced-rib type for railroad bridges of 200-ft. span is more economical than the solid-rib type; and the divergence of cost between them will augment as the span increases. It is probable that it will diminish somewhat for spans down to 100 ft. (at which length simple, plate-girder spans would be preferable); but it is not likely that, for railroad structures, the solid-rib type will in any case be quite as economical as the braced-rib type.

In making the calculations for Problem No. 7, as previously stated, it became necessary to compute the weight of metal for a 500-ft., spandrel-braced, three-hinged arch; and by a little extra computation it was practicable to compare the total weights of metal in braced-rib and spandrel-braced arch bridges for double-track, steam-railway structures of that span; but it was necessary to include the floor metal, because of the longer panels in the spandrel-braced structure. The latter required about 7% more metal than the braced-rib structure; but a revised set of computations, with more nearly equal panel-lengths, would probably have reduced that difference somewhat, although it certainly could not have lowered it more than 2 or 3% of the total weight per foot.

Concerning the economics of the spandrel-braced arch, as compared with the braced-rib structure, it appears, therefore, that it is a little lighter for the 200-ft. span and a little heavier for the 500-ft. span; but, if the arch is to be erected by cantilevering, the saving in weight of erection metal will nearly always make the spandrel-braced structure the more economical.

PROBLEM NO. 5.

Up to the present time, the comparative economics of hingeless, two-hinged, and three-hinged arches have been absolutely undetermined, as is shown by the diametrically opposed views of a number of engineering writers. Merriman and Jacoby claim that, in their analysis of the two-hinged, spandrel-braced, arch bridge at Niagara, they found a saving of main sections amounting to 0.8% by the use of a crown-hinge in the lower chord, one of 8.8% by placing it midway between the chords, and one of 11.8% by putting it in the upper chord. Again, the late F. C. Kunz, M. Am. Soc. C. E., a high authority on bridges, in a letter to the writer, gave two formulas for weights of metal in two-hinged arches and their lateral bracing, and stated that for three-hinged arches such weights may be reduced 15 per cent.

On the other hand, Malverd A. Howe, M. Am. Soc. C. E., found, for a 416-ft. arch bridge, having a 67-ft. rise, the following relative weights of metal:

Hingeless type	1.00
Two-hinged type	1.21
Three-hinged type	1.30

Joseph W. Balet claims* that there is no difference in the economics of the two-hinged and three-hinged arches, but that the hingeless type is more economical than either.

Again, Willis Whited, M. Am. Soc. C. E., is quoted† as stating that "an arch without hinges, or with only two hinges at the ends, has less material and looks better than a three-hinged arch".

From the preceding it would appear that there is a strikingly great uncertainty about the economic effect of the hinging of arches; and, in consequence thereof, the writer has prepared diagrams of stresses and sections for 500-ft. arch bridges, first, for the three-hinged type to carry the steam-railway load hereinbefore specified, then a similar structure to carry the highway and electric-railway loadings, also previously indicated; second, for the corresponding two-hinged type of structure with both loadings; and, third, for the corresponding hingeless type of structure, also with both loadings.

In order to save time, the intensity for chord members was assumed for all cases to be 14 000 and that for web members 12 000 lb. The

* "Analysis of Elastic Arches."

† In Tyrrell's "History of Bridge Engineering."

former intensity is for compression only (for which kind of stress the chords were always proportioned); but the latter intensity applies to both tension and compression, because it allows about the right amount for area lost by rivet holes, and conforms for web members in compression quite accurately with the formula,

$$C = 16\,000 - 60\,\frac{l}{r}.$$

After all the diagrams of sections were completed, the correctness of these assumed intensities was checked, and the results were found to be exceedingly close, the average error for all six designs being only 1%, and the maxima 4% on the side of safety and 2% on the side of danger. Moreover, these variations affected the various types about alike, hence the approximate assumptions do not tend toward any unfairness in the comparison of weights.

There was another short cut made that involves a slight error in the total weight of web metal; but it affects all cases to the same extent. It is the use of a single value of impact for all the truss members of the span, instead of varying it for each web member according to the length of span covered by the moving load when the said member receives its greatest stress.

The weights of the main members in all six cases were computed, and the details were properly allowed for by percentage, due cognizance being taken of the weights of the special details at the hinges and of those at the anchorages. In the hingeless and the two-hinged types the temperature stresses were computed for a variation of 60° Fahr. above and 60° below normal; but when temperature stresses were added to those due to live load, impact, and dead load, the intensities of working stresses were increased by 20 per cent. As the spandrel columns and their bracing would average in length about the same for all three types, the weights of these parts of the structure were not considered, and only those of the arch-ribs were compared.

It was found that the economics of the three types depend mainly on two important features of the designing specifications, *viz.*, the method of treating reversing stresses, and the importance accorded to temperature stresses. If the effect of stress reversion is entirely ignored, the hingeless and the two-hinged structures will be lighter than the three-hinged one; but if each section on which there is reversion is computed for the greater stress plus 50% of the smaller

one, which is in conformity with many of the best modern bridge specifications, there is only a small advantage in favor of the two-hinged type over the three-hinged. Probably, if the percentage were 75, instead of 50, as some engineers specify, the weights would be alike for the two types.

If temperature stresses are entirely ignored, the two-hinged type will have an advantage of about 7% over the three-hinged type; but if they are provided for without augmenting the intensities of the working stresses, there will be a 7% advantage for the three-hinged type. If the intensities for the combination of the stresses due to all the loadings and the temperature effects are increased 20% above normal, there is an advantage for the two-hinged type of 5% or more. Probably, if the increase of intensity above normal were 10% instead of 20, the weights of metal for the two types would be about equal. As it is logical to allow a 20% increase of intensities for the combination, it is evident that, for 500-ft. spans, the two-hinged type, as far as weight of metal is concerned, has the advantage over the three-hinged. The exact figures for the comparison are as given in Table 6.

TABLE 6.

Character of structure.	Number of hinges.	Weight of metal, in pounds per linear foot per side.	Comparative percentage.
Railway	3	2 180	100
Railway	2	2 075	95
Railway	0	2 295	105
Highway	3	1 230	100
Highway	2	1 134	92
Highway	0	1 250	102

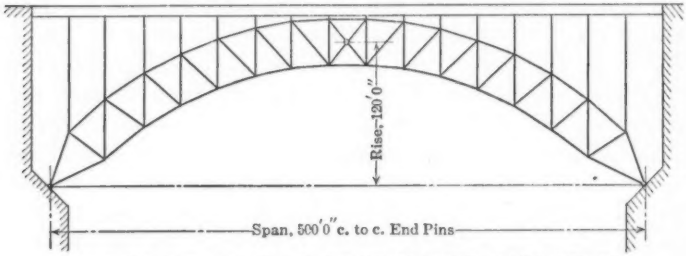
In the comparison in Table 6 the effects of wind loads have been ignored, for two reasons: first, because it is probable that they would be so small as to have no influence on the sections after allowing the usual 30% excess for the intensities of working stresses; and, second, because any small variations they might involve would be practically of like kind and amount for all cases.

Fig. 8 is the layout for the three-hinged and two-hinged arches of 500-ft. span, and Fig. 9 is that for the corresponding hingeless structure.

It might be well to call attention to the fact that in retaining the same outline for the ribs of the 500-ft., two-hinged arch as adopted

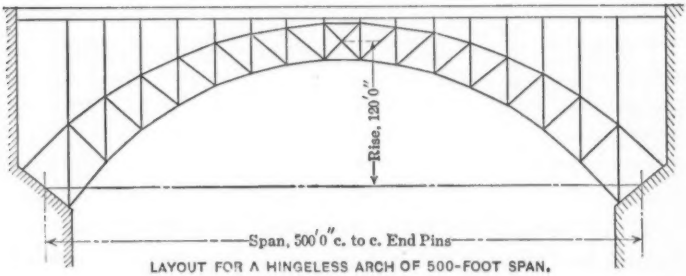
for the corresponding three-hinged structure, a slight injustice has been done to the former type, because its approximately economic shape is that of a crescent; but the difference in weight involved by this variation from the ideal is small. The reason for ignoring it is the saving in labor involved in making computations by assuming the two outlines to be identical.

Again, it is possible that the layout for the hingeless type is not the most economical one that can be drawn; but it is thought to be



LAYOUT FOR THREE-HINGED AND TWO-HINGED ARCHES OF 500-FOOT SPAN.
(In the three-hinged arch the chords in the middle panel are false members)

FIG. 8.

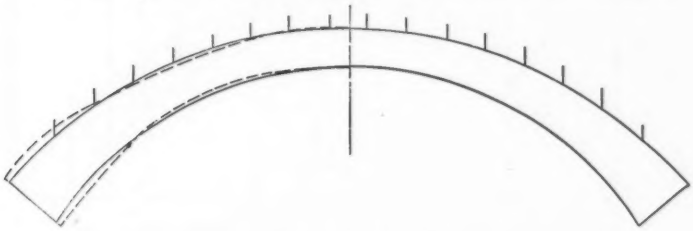


LAYOUT FOR A HINGELESS ARCH OF 500-FOOT SPAN.

FIG. 9.

so close to it as not to affect the economic comparison materially. A small quantity of metal might have been saved by adopting an outline somewhat like that which Gustav Lindenthal, M. Am. Soc. C. E., for motives of esthetics and of suitability to meet existing conditions, but assuredly not for those of economy in weight of metal, used for his two-hinged Hell Gate Arch Bridge. The rib outlines of that long span are, generally speaking, economically appropriate for a hingeless arch, but not for one with hinges at the springing points.

As an approximate test of the correctness of the assumed outline for the 500-ft., hingeless, arch span, find the average of the rib depths at all the panel points and call the result d_a; then compute the average of all the proportioning bending moments at these panel points, and call the result M_a. If M is the proportioning bending moment at any panel point (that is, the larger moment plus one-half of the smaller moment of the opposite sign), find the ratio, r, of $\frac{M}{M_a}$ for each panel point, and multiply it by d_a, then lay out the resulting depth symmetrically above and below the center line of the arch, and join the points thus determined, so as to form new chord center lines. This has been done, as shown in Fig. 10, from which it will be seen that, for five and a half panels on each side of the crown, the

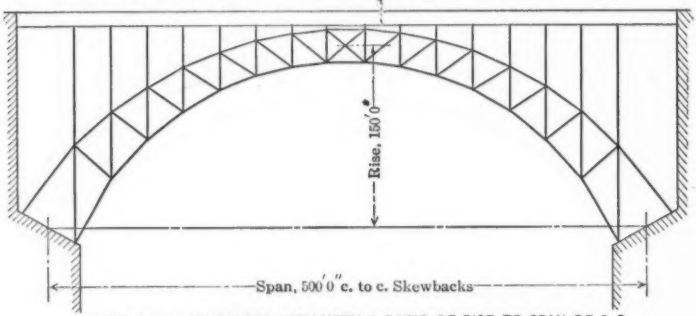


LAYOUT FOR A HINGELESS ARCH OF 500 FEET SPAN, SHOWING MODIFICATION FOR DEPTHS PROPORTIONATE TO ADJUSTED BENDING MOMENTS.
(Solid lines represent original outline as adopted for design, and dotted lines represent modified ideal outline.)
FIG. 10.

curve was drawn just about right, but for the remaining three panels the rib depth should have been greater. As it is not absolutely essential that the rib depth at all points be exactly proportional to the adjusted bending moment, it will suffice to adopt a certain depth at the ends and about half as much at the crown, and run in approximately parabolic curves accordingly.

From Table 6 it seemed likely that, for 500-ft. spans, there is no economy in the hingeless arch as compared with arches having either two or three hinges. However, it was deemed possible that a greater rise might reduce the temperature stresses so as to lower materially the total weight of metal in the hingeless arch. A rough test of this point was made by assuming the rise of the 500-ft. arch to be increased 30 ft., or from 0.24 to 0.30 of the span length, with the result that the

weight of metal was reduced about 7.5% by diminishing the prejudicial effect of the temperature stresses, but was increased about 7% by reason of the greater length of the arch rib, leaving the possibility of some economy by the reduction of stresses from live and dead loads. It was then decided to make an exact determination of the effect of the increased rise, on the layout shown in Fig. 11, even at the expense of 3 days' work for a computer, by making a complete determination of stresses and sections and estimating therefrom the weight of metal. From this it was ascertained that for the arch alone the saving effected amounted to 6%; but, when the proper addition was made for the superimposed columns and their bracing, the gain was exactly exhausted by the increased height from springing point to grade.



LAYOUT FOR A HINGELESS ARCH WITH A RATIO OF RISE TO SPAN OF 0.3

FIG. 11.

It was evident, though, that if the rise of 150 ft. was fixed for the 500-ft. span, the hingeless arch might possibly prove more economical than the three-hinged one; hence, a comparison was made, with the result of a difference of one-half of 1% in favor of the three-hinged type.

The combined highway and electric railway, hingeless arch, with 150 ft. of rise, was also computed, but the saving in the arch alone, as compared with the corresponding span of 120 ft. rise, was only 3%, which was not enough to offset the increase in the weight of spandrel columns and their bracing.

From the four designs (railway and highway) for the 500-ft. span, hingeless arches, there can be drawn a deduction of some value, *viz.*, the manner in which the economics of structures of that type, as compared with three-hinged arches, vary with the ratio of live load plus

impact to total load. In the case of the railroad structure, that ratio is 0.645; and in that of the highway structure it is 0.351. In Fig. 12 the abscissas represent the ratios of live load plus impact to total load, and the ordinates indicate the ratios of weights of metal in hingeless arches to the weights in corresponding three-hinged structures. The right line on the diagram was plotted solely by the two ratios thus determined; and it is assumed to apply properly for all

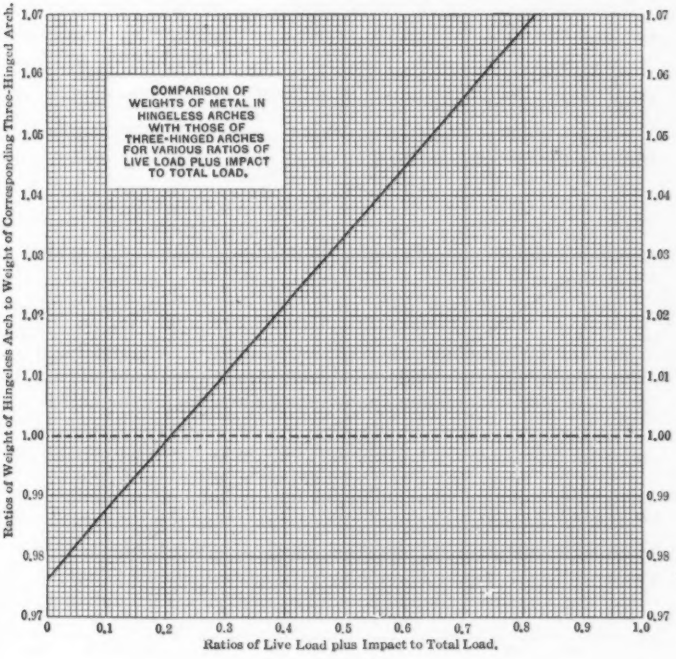


FIG. 12.

spans and loadings, for the following reason: The sole cause of the variation of the economics in the two 500-ft. span, hingeless arches is the factor of the ratio of live load plus impact to total load. Hence, if we know, for several widely divergent span lengths, the ratios of live load plus impact to total load (as can readily be determined for any feasible span by the use of the ten equations previously mentioned, and the numerous diagrams of weights of metal per linear foot of

span)* we can determine, for steam-railway bridges, and for the type of combined highway and electric-railway bridges herein adopted as standard, the economics of hingeless and three-hinged arches. This has been done; and the results have been plotted in Fig. 13, in which the abscissas represent span lengths for arch bridges up to a limit of 1 000 ft., and the ordinates indicate the ratios of weights of metal in

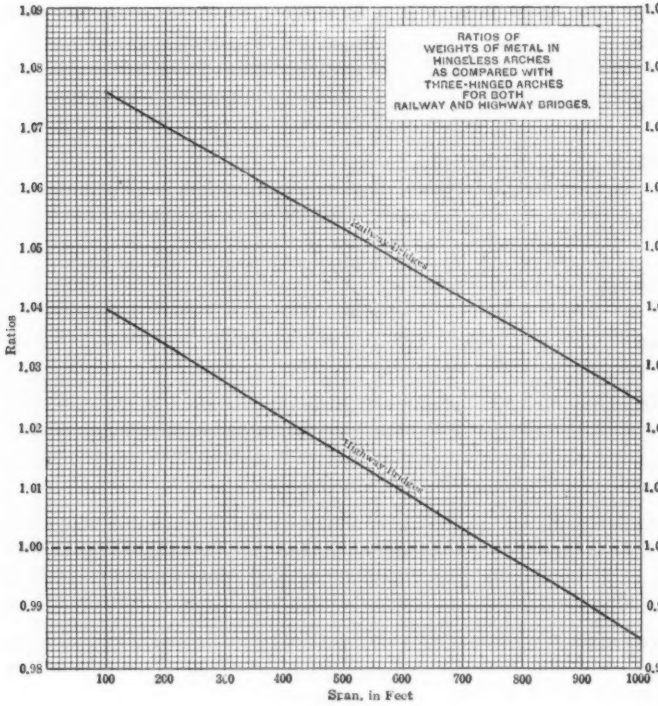

FIG. 13.

hingeless arches as compared with those of the corresponding three-hinged structures. Although the upper line of the diagram was plotted from data obtained for double-track bridges, no error of any magnitude will be made by assuming that it holds good for all strictly railway structures; and the lower line may be used safely for all modern

* Given in Chapter LV of "Bridge Engineering".

highway bridges with paved floors supported by reinforced concrete bases and having concrete sidewalks.

Based on the numerous weight computations made specially for the preparation of this paper, the following formulas for weights of metal in the arches alone, per linear foot of span, in arch bridges of the several types, have been established:

For Three-Hinged Arches.—

$$W_a = (0.000282\ D + 0.000426\ L)\ l \ldots\ldots\ldots\ldots (2)$$

For Two-Hinged Arches.—

$$W_a = (0.000248\ D + 0.000416\ L)\ l \ldots\ldots\ldots\ldots (3)$$

For Combined Two-Hinged and Three-Hinged Arches.—

$$W_a = (0.000282\ D + 0.000416\ L)\ l \ldots\ldots\ldots\ldots (4)$$

For Hingeless Arches.—

$$W_a = (0.000272\ D + 0.000460\ L)\ l \ldots\ldots\ldots\ldots (5)$$

These four formulas are based on the writer's published designing specifications, which treat reversing stresses by adding one-half of the smaller stress to the larger stress and proportioning for the sum; but if the effect of reversion is entirely ignored, as some engineers deem proper, these formulas will reduce to the following:

For Three-Hinged Arches.—

$$W'_a = (0.000292\ D + 0.000396\ L)\ l \ldots\ldots\ldots\ldots (6)$$

For Two-Hinged Arches.—

$$W'_a = (0.000258\ D + 0.000380\ L)\ l \ldots\ldots\ldots\ldots (7)$$

For Combined Two-Hinged and Three-Hinged Arches.—

$$W'_a = (0.000292\ D + 0.000380\ L)\ l \ldots\ldots\ldots\ldots (8)$$

For Hingeless Arches.—

$$W'_a = (0.000270\ D + 0.000398\ L)\ l \ldots\ldots\ldots\ldots (9)$$

In Equations (2) to (9), inclusive, W_a, or W'_a, is the weight of metal, in pounds per linear foot of span, in the arches of the structure; D is the dead load, in pounds per linear foot of span; L is the live load plus impact, in pounds per linear foot, used in making the calculations; and l is the span length, in feet. These eight equations will give fairly

accurate results (slightly on the side of safety) for ordinary conditions which do not vary greatly from the theoretically economic ones.

In computing the value of L for insertion in Equations (2) to (9), inclusive, the equivalent uniform live load and the impact should be determined for the half-span length, as herein previously indicated.

In order to show that the writer's past surmises concerning the economics of the hingeless type of arch were not far wrong, he takes the liberty of quoting the following:*

"It is claimed that hingeless arches require less metal than any other type; but the author, upon general principles only, is inclined to disagree with that opinion. He has never had occasion to design an arch without hinges, but feels quite confident that if he should ever figure one, he would find that a proper provision for excessive temperature stresses, possible large indeterminate stresses, unusual detailing, heavy anchor-bolts, and an inherent sense of fitness in proportioning sections, would so increase the weight of metal as to absorb all of the theoretical economy over the three-hinged arch involved by the smaller average direct stresses as shown on the stress sheets."

PROBLEM NO. 6.

From the calculations for the two-hinged and three-hinged types, it was easy to compute the stresses and sections for a combination of the two, making the structures three-hinged for the dead loads and two-hinged for the live loads. The results showed, as was anticipated by *a priori* reasoning, that the combination produces weights of metal intermediate between those of the two types previously computed. The exact results are given in Table 7.

TABLE 7.

Character of structure.	Weight of metal, in pounds per linear foot per side.	Percentage compared with three-hinged structure.
Railway arch.....	2 108	97
Highway arch.....	1 212	99

From Tables 7 and 6, it will be seen that there is an increase of weight of 2% for the railway structure and of 7% for the highway structure in the combination, as compared with the two-hinged type; but the resultant excess of cost will generally be considered of small importance in comparison with the value of the certainty of the dead-

* From p. 621 of "Bridge Engineering."

load distribution effected by the hinging, combined with a reduction in the difficulty and expense of erection.

As compared with the three-hinged arch, the combination type affords greater rigidity under moving load—an especially important feature in railroad bridges. Again, the erection problems are less difficult, and therefore less expensive, for three-hinged than for two-hinged arch structures.

Problem No. 7.

The solution of the problem of determining the economics of the cantilever-arch bridge was accomplished thus:

First.—A design was made for a three-hinged, spandrel-braced, double-track railway, arch bridge of 500-ft. span and of approximately economic rise; and the weight of metal for the arches thereof was then computed.

Second.—Simple-truss flanking spans, each 292 ft. long, were added, resting at their outer ends on rollers, and attached at their inner ends to the vertical end-posts of the arches; and the weight of metal for these flanking spans was calculated.

Third.—It was assumed that the arches were cantilevered out for three of the seven panels, and that the remaining four panels formed the suspended span; then the weights of both the arch span and the flanking spans were computed. This layout was deemed in advance by the writer to be the most economic one possible.

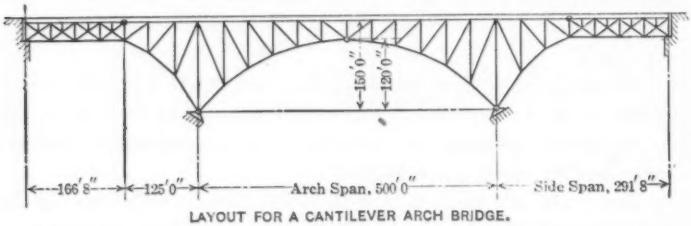
Fourth.—Next, the number of panels in each cantilever arm was reduced to two; and, as before, the weights of metal in all spans were calculated.

Fifth.—Finally, the number of panels per cantilever arm was increased to four, and the work of computation was repeated.

As surmised, there was quite an economy of metal by cantilevering, and the three-panel, cantilever arms proved to be the most economical, the saving of metal in the arches and trusses combined being about 11 per cent. There was a small increase, instead of a reduction, of weight of metal in the arch, but the economy in the flanking spans was quite marked. The best lengths of cantilever arm and suspended span were, respectively, about 40 and 60% of the total length of one flanking span. The layouts for two of these computed structures are shown in Figs. 14 and 15, the former being for the cantilever arch, and the latter for an ordinary arch with flanking simple-truss spans.

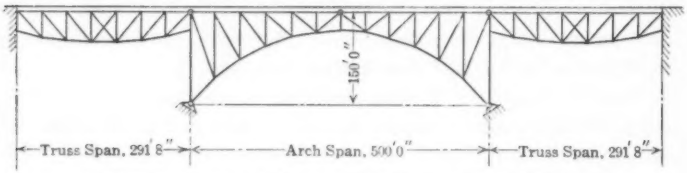
It was thought possible that a different length of flanking span would entail different results; hence, the length was reduced to 208 ft., and the calculations were repeated. As in the last case, there was a saving in the combined weights of arches and trusses, but not so pronounced an economy as before; however, the economic ratios for cantilever arm and suspended span to total length of flanking span remained unchanged, being, respectively, about 0.4 and 0.6.

It was for convenience of computation that the arches in these comparisons were made three-hinged; but, it is evident, after giving the question a little thought, that the conclusions reached would have been practically the same had the arches been two-hinged. Hingeless arches, of course, are not suitable for the cantilevering of flanking spans.



LAYOUT FOR A CANTILEVER ARCH BRIDGE.

FIG. 14.



LAYOUT FOR AN ARCH BRIDGE, WITH FLANKING SIMPLE-TRUSS SPANS.

FIG. 15.

PROBLEM NO. 8.

A few years ago the writer made an attempt to obtain, by correspondence with a large number of bridge engineers, some reliable data relating to the ratios of weights of metal in arch bridges and truss bridges of the same span length and the same live-load carrying capacity; but he was unsuccessful, as nothing reliable on the subject was known to the Engineering Profession. However, from the numerous calculations made for this paper, combined with weights of simple-truss spans previously published by the writer, there has been prepared the diagram, Fig. 16.

The right lines plotted thereon coincide with those recorded by the following equations:

For Steam-Railway Structures.—

$$P = 106 - 0.08\ S \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

For Electric-Railway Structures.—

$$P = 93 - 0.07\ S \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

For Highway Structures.—

$$P = 80 - 0.056\ S \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

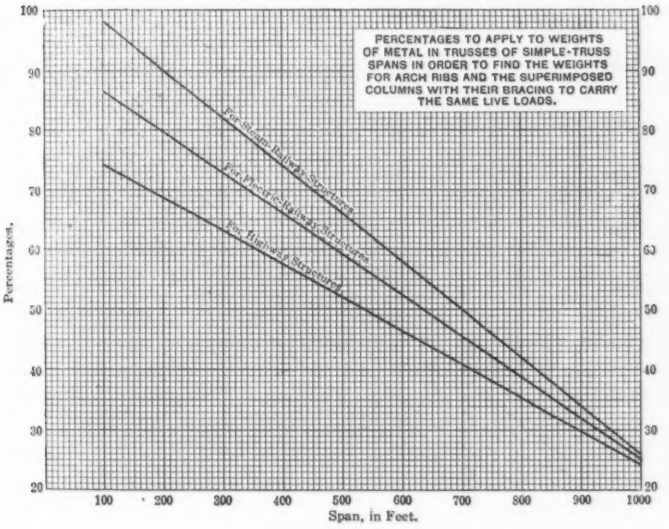


FIG. 16.

In these equations, S is the span-length, in feet; and P is the percentage to apply to the weight of metal in the trusses of any simple-truss bridge, in order to ascertain the weights of corresponding arches and the superimposed columns with their bracing. It must not be forgotten that the superior limit of S in these two equations is about 1 000 ft., which is as far as the recorded weights of simple-truss spans are carried, and that the inferior limit is 100 ft. The two exterior lines of the diagram were computed, but the middle one was interpolated by judgment. None of them can be considered as strictly

accurate for all cases, because of the influence of varying conditions precedent.

From Fig. 16 and Equations (10) and (12) it is evident that the arch is more economical for combined highway and electric-railway bridges than for steam-railway structures. This is because of the

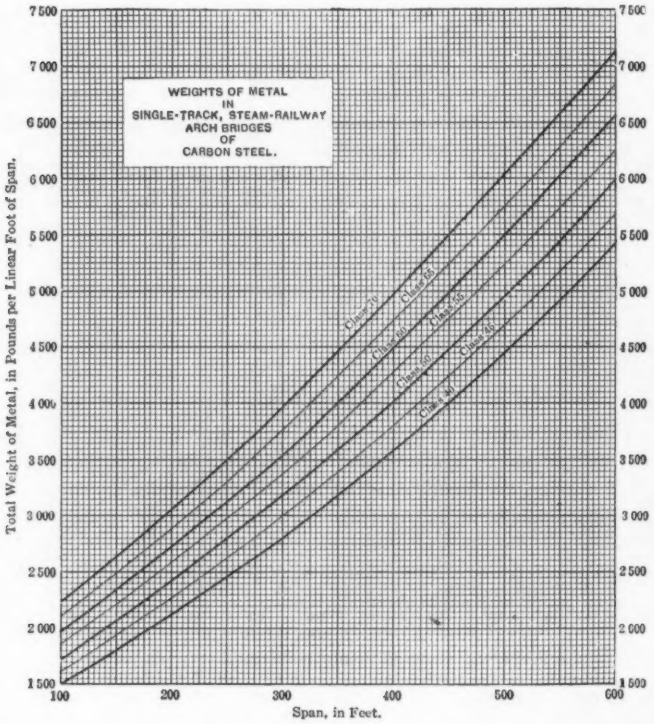

FIG. 17.

smaller ratio of live load plus impact to total load in the former. The larger the dead load of the flooring and floor system, the more advantageous is it for the arch structure in comparison with the truss bridge. In the double-track, steam-railway bridges of this investigation, the floor weight per linear foot of span is about 2 200 lb., and in the 60-ft. wide, highway and electric-railway bridge thereof, with its paved floor,

reinforced concrete base, and reinforced concrete sidewalks, it is about 6 400 lb. In Fig. 16 the converging of the three right lines as the span length increases is due to the augmenting influence of the dead load.

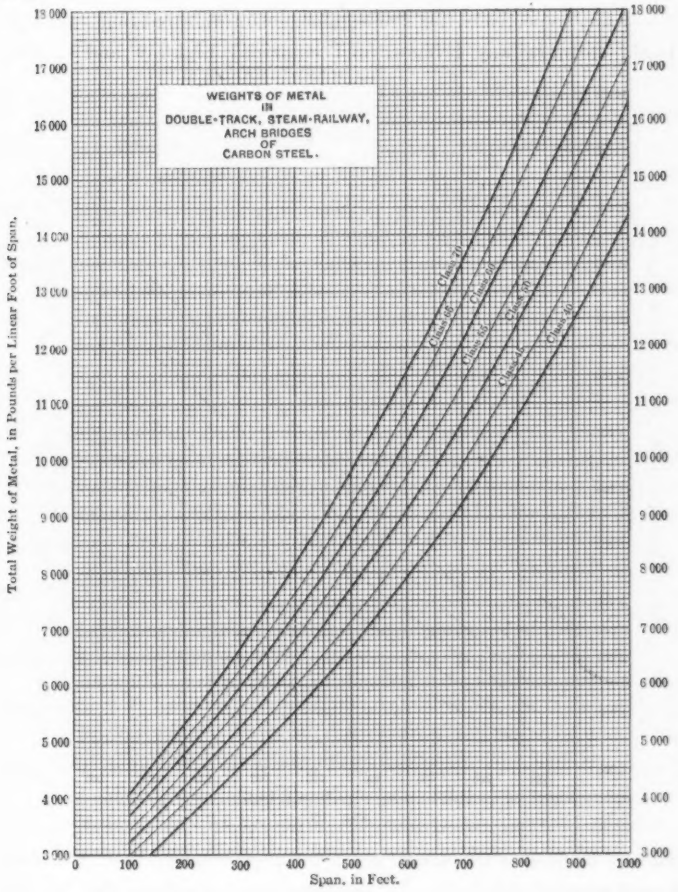

FIG. 18.

No comparison has been made between the weights of solid-rib arches and those of the corresponding truss spans, because such a comparison would seldom be of any use.

By using the percentages shown in Fig. 16 and certain diagrams of weights of metal previously published by the writer, there have been prepared the diagrams of total weights of metal per linear foot of span for three-hinged, braced-rib, arch bridges, shown in Figs. 17, 18, and 19. These are, respectively, for single-track, steam-railway bridges; double-track, steam-railway bridges; and combined highway and electric-

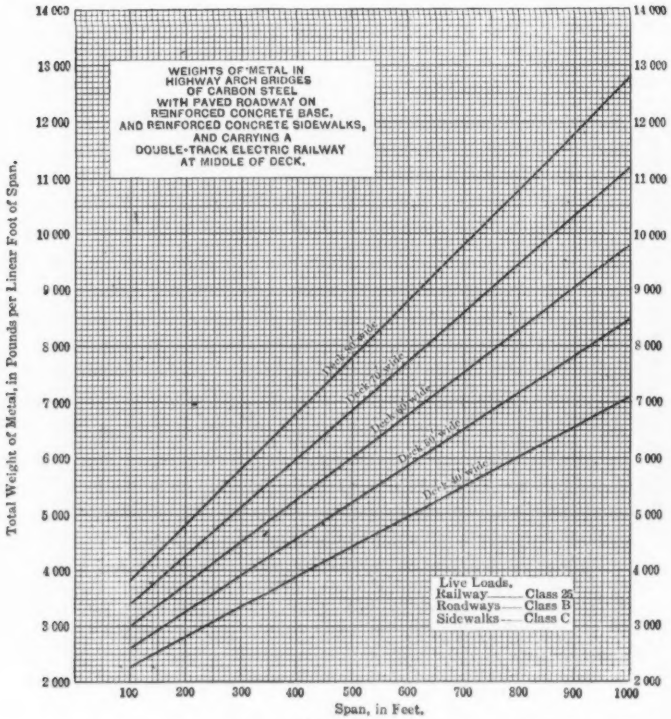

FIG. 19.

railway bridges, with paved floor, reinforced concrete base, and reinforced concrete sidewalks. In preparing these diagrams, due account has been taken of the splaying of the columns in the bents carrying the floor. If these diagrams are to be used for spandrel-braced arches by making a small percentage reduction or addition, based on the deduc-

tions in Problem No. 4, it will be necessary to multiply the result thus found by the secant of the angle which the splayed spandrels make with the vertical. In order to determine the proper splay for any case, one should remember that the width of structure at the springing should never be less than 30% of the vertical distance from the springing point to grade, and, preferably, not less than 35% thereof.

For weights of metal in multiple-track, arch structures, no error of any importance will be made by assuming them to be directly proportional to the number of tracks (using the double-track records of

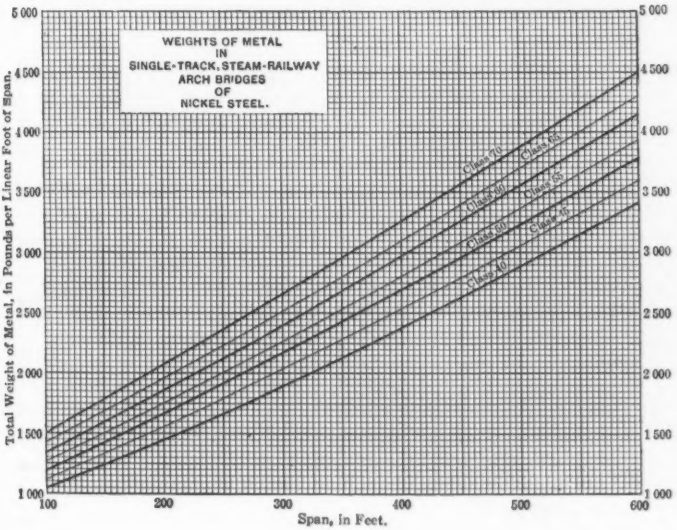

FIG. 20.

Fig. 18 as a basis); and for strictly highway arch structures of similar construction throughout, by taking them proportional to the out-to-out width of the deck. In Fig. 19 this proportionality does not hold, because the structures therein diagrammed carry at mid-deck a double-track, electric railway.

It seems hardly necessary to state that for hingeless, two-hinged, and combined three-hinged and two-hinged arches, the total weights of metal per linear foot of span may be readily obtained by applying to the weights, found from Figs. 17, 18, and 19, the small percentage

corrections for arch weights hereinbefore determined in the discussion of the economics of the different types, using Equation (2) for finding these arch weights.

It may be of interest to some engineers to know the weights of metal in steam-railway, arch bridges built of nickel steel; consequently, the diagrams, Figs. 20 and 21, have been prepared for single-track and double-track, arch structures, respectively. It seems hardly worth

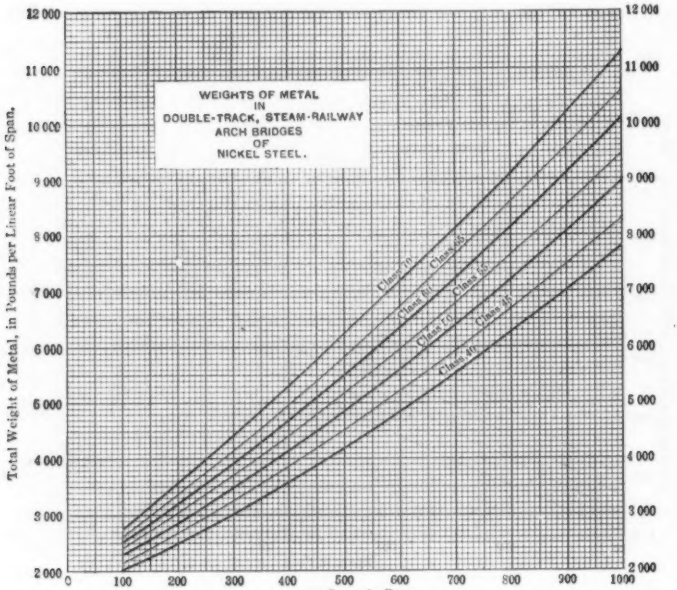

FIG. 21.

while, however, to give diagrams for highway, arch bridges of nickel steel, because of the uncertainty as to the extent to which the alloy would be used in any particular structure. For bridges of comparatively short span lengths, it might be economical to use it in the arches only; in long spans, in which the importance of reducing the dead load is paramount, it would pay to use it in the floor system also; but in very few cases is it ever advisable to adopt the alloy for the lateral system, on account of the fact that the proper minima sections of

carbon steel generally provide an excess of strength for the computed wind stresses.

From the formulas herein given for weights of arch ribs, some interesting deductions may be drawn. For instance, in Equation (2), *viz.*,

$$W_a = (0.000282\ D + 0.000426\ L)\ l,$$

the dead load, D, is composed of the rib weight, W_a, plus the weight

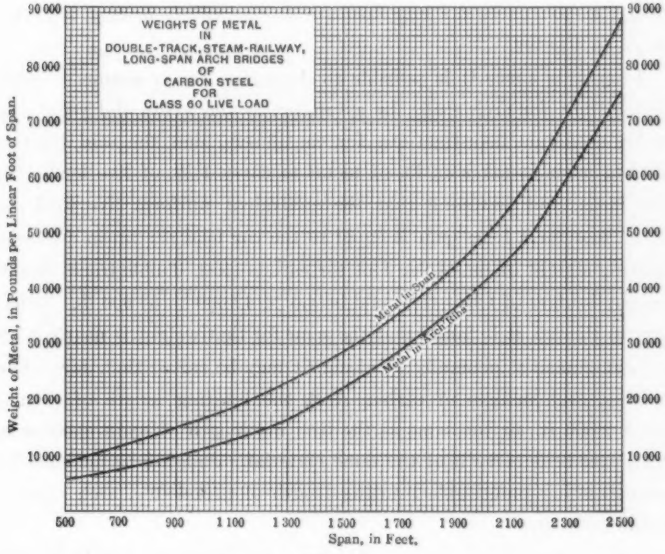

FIG. 22.

of floor, columns, lateral system, etc., all of which may be grouped under the symbol, W', making the equation

$$W_a = (0.000282\ W_a + 0.000282\ W' + 0.000426\ L)\ l.$$

Solving this gives:

$$W_a = \frac{(0.000282\ W' + 0.000426\ L)\ l}{1 - 0.000282\ l}.$$

In order that W_a may be infinitely great, the divisor of the second term must be equal to zero, or

$$l = \frac{1}{0.000282} = 3\,540 \text{ ft.}$$

This is the theoretical limiting span for three-hinged arches of carbon steel, or the span at which such an arch could carry nothing but its own weight without being over-stressed. It will be noted that this limiting length is the reciprocal of the dead-load coefficient in Equation (2), and that a vertical line on the diagram of arch rib weights per linear foot of span, drawn through the abscissa point which represents this value of l, will be asymptotic to the weight curve. Such a weight curve for long spans of steam-railway bridges is partly shown in Fig. 22.

From this curve it is possible to determine the economic or practicable limit for arch spans, by assuming, as the writer did years ago, in his economic investigations for cantilevers, that the said limit is reached when it takes $4\frac{1}{2}$ lb. of metal to carry 1 lb. of live load. On that basis, and assuming that the equivalent uniform live load per linear foot for a long span is equal to the car load per linear foot, the limiting weight of metal per foot for carbon-steel, double-track, steam-railway bridges of Class 60 would be $4.5 \times 12\,000 = 54\,000$ lb. Referring to Fig. 22, it is found that the span for that weight is nearly 2 100 ft.; consequently, generally speaking, it may be stated that, for steam-railway, arch bridges of carbon steel, the limiting length of span is about 2 000 ft., or the same as the limiting length of main opening in cantilever bridges built of the same material. Judging by analogy, the corresponding practicable limiting length of nickel-steel arch spans is about 2 600 ft.

The various formulas and diagrams in this paper are to be considered as merely approximate; and though they are sufficiently accurate for preliminary estimates and for obtaining trial dead loads, they should not be used by contractors in tendering on work. The reason for this uncertainty is that the varying physical conditions at different crossings affect the arch layouts to such an extent as materially to influence the weight of metal required. As the formulas were based on economic functions, the weights given by their use might very properly be considered as the minima possible; and any uneconomic conditions which may exist will involve an increase thereof, the amount being a matter to be determined by the computer's judgment.

Résumé of Results.

The following is a condensed statement of the principal findings from all the preceding investigations, recorded in the previously indicated order of the problems set for solution:

First.—For three-hinged arches with the grade line approximately tangent to the top chord of the arch at the crown, the average economic ratios of rise to span length are as follows:

Solid-rib structures	0.2
Braced-rib structures	0.225
Spandrel-braced structures (with hinge above)	0.25

These values may be either increased or decreased by 0.025 without making any material difference in the economics.

For three-hinged half-through, arch bridges, the average economic ratios of rise to span-length are as follows:

Solid-rib structures	0.225
Braced-rib structures	0.3

For three-hinged, high-deck, arch bridges, they are as follows:

Solid-rib structures	0.25 to 0.28
Braced-rib structures	0.33 to 0.38

For two-hinged arches and combined two-hinged and three-hinged arches, the economic ratios of rise to span will be practically the same as for three-hinged structures.

For the hingeless arch, a somewhat greater ratio of rise to span than that for the three-hinged arch is economical. The single test of this made for the 500-ft. span indicates that the best ratio is about 0.28 with low-grade deck, 0.33 for half-through arches, and 0.38 with high-grade deck.

Second.—In respect to solid-rib arches, the question of economic depth of rib does not arise; for the depth should always be made as great as a proper consideration of the section for resisting compression will permit. For braced-rib, three-hinged arches the economic rib-depth is about 7.5% of the span length, but quite a variation from

that percentage may be made without materially increasing the weight of the metal.* The economic average depths for hingeless and two-hinged arches will be about the same as the economic depths for three-hinged arches. The best form for a two-hinged arch is the crescent shape, but there is no great economy in this over the rib with uniform depth. The best shape for the hingeless arch is secured by making the depth at the crown about one-half of that at the springing points. Such a layout, as shown in Fig. 11, tends not only toward uniformity of chord section, but also toward esthetics.

Third.—It was found for all cases that the most economic location for the crown-hinge in a spandrel-braced arch is in the top chord. In braced-rib and solid-rib arches, however, the hinge should always be placed at mid-depth, so as to distribute properly the thrust over the two chords.

Fourth.—Comparing the economics of solid-rib, braced-rib, and spandrel-braced arches, it was found that the first mentioned is always considerably heavier than either of the others; and, under normal conditions of the metal market, it is also more expensive. The spandrel-braced arch requires for long spans a little more metal than the braced-rib arch; but, in case of cantilevering, this would generally be offset by the extra quantity of erection metal needed for the braced-rib structure. In short spans, the spandrel-braced arch is a trifle the lighter.

Fifth.—Comparing three-hinged, two-hinged, and hingeless arches, it was found that the three-hinged is a little heavier than the two-hinged, but nearly always lighter than the hingeless. The variations in weight among the three types, however, are never great.

Sixth.—The combination of three hinges for dead load and two hinges for live load produces very little saving over the three-hinged type; but it adds materially to the rigidity. In the writer's opinion, the combined type is preferable to any of the others.

Seventh.—When an arch is flanked by other spans than arches, there is generally quite a little economy involved by cantilevering the ends of the arch and shortening the lengths of the simple spans. The best proportions for lengths of cantilever arm and suspended span to total length of flanking span are, respectively, 0.4 and 0.6.

* For a modification of this see the résumé of the discussions.

Eighth.—The ratios of weights of arches to the weights of the corresponding simple spans for both railway and highway bridges have been determined and plotted. As was anticipated, the arch usually effects a greater relative economy in highway structures than in railway structures of the same span length; and, the longer the span the greater always is the proportionate saving of metal.

As a conclusion to this paper, the writer begs to quote from one of his previous publications as follows:

"In dealing with the comparative economics of arches and simple trusses, it must not be forgotten that there are other factors than mere weight of metal involved; for the pound price of the manufactured material is generally somewhat greater for the former, and sometimes the cost of erection also is larger. Again, the comparison of the costs of arch superstructures and truss superstructures alone is not of much importance; for an economic investigation, to be of any value, must include both substructure and superstructure; and the costs of the former are likely to be very different in arch designs and simple-truss designs for any crossing".

The thanks of the writer are due to D. B. Steinman, Assoc. M. Am. Soc. C. E.,* one of the associate engineers of his firm, for expert assistance in making certain graphic calculations by which a number of important points of economics determined in this paper were solved.

* Now M. Am. Soc. C. E.

DISCUSSION

Mr. Blackwell.

PAUL A. BLACKWELL,* ASSOC. M. AM. SOC. C. E.† (by letter).—The author has again enriched engineering literature by his latest contribution, "The Economics of Steel Arch Bridges." Any one who has had to do with arch work knows the difficulty of getting working data from the mass of mathematical information on this subject. This has resulted in the decision of the average engineer to steer clear of arches of all descriptions, because they are difficult to calculate; and that there ever were any economical considerations applying to structures of this type, probably never entered his mind.

It is true that arches are generally built as monuments, or for advertising purposes, and are chosen for these purposes because they are easily adapted to esthetic treatment; and, in view of their use only as monuments, the question of economy has hardly been considered.

Several years ago the writer, having in view something of what the author has brought out, endeavored to make a comparison between the economical advantages of the generally accepted three types of arch. Reducing the results that were found to the same classification as given in this paper, the writer will comment as follows:

First.—In reference to the economic ratio of rise to span, it seems to be the consensus of opinion that the correct ratio is about 1:5. This agrees with the ratios given, although this, like everything else that has to do with bridge work, must depend on what can be done, and not always on what should be done; and, of course, as the type of arch chosen must be the best suited for the place, the ratio of rise to span is not dependent on the type.

Second.—The writer takes exception to the following statement: "As far as solid-rib arches are concerned, the question of the economic depth of the rib does not arise." As so many things enter into the problem—one of which is shipping—the available depth is often determined. This may not be the theoretical economical, or least-weight, depth; but, when ease of manufacture, obtaining material, and ease of erection are considered in their relative importance as economical factors, the limit of the solid-web arch is reached with about a 10-ft. web, which would correspond to a probable maximum span of 400 ft. In nearly all existing arches the general practice has been to make the depth of ribs about one-twenty-fifth to one-fiftieth of the span. The writer generally uses one-fortieth, about one-third of what the author finds as the economical depth. A depth of 60 ft. for an 800-ft. arch rib would require members of the webbing about 80 ft. long. These members carry comparatively small stresses, and, in order to be so long, would have to be very large to have sufficient stiffness, and would probably be as large as the chords themselves. This would

* Roanoke, Va.

† Now M. Am. Soc. C. E.

not be economical; besides, the appearance of the arch is improved by reducing the depth of the web. Varying the shape of the hingeless arch (widest at the ends) adds to the appearance and results in economy of material. Mr. Blackwell.

Third.—The writer does not believe that there is any economy in putting the crown-hinge in the top chord. Generally, a neater detail, and a more easily erected and better looking structure results from placing the crown-hinge in the bottom chord (for spandrel-braced arches). In all other cases the crown-hinge should be placed as the author recommends.

Fourth.—The writer believes the spandrel-braced, two-hinged arch, of moderate span, to be the most satisfactory structure for railway traffic, when an arch is necessary or desired; but, for highway structures, should the condition allow, an arch-rib structure is better.

Fifth.—The writer has found that the three-hinged arch is the heaviest type; the two-hinged and hingeless are of about the same weight. The hingeless arch is the stiffest, but, in order to make the ends truly fixed, there is no economy in weight over the two-hinged arch.

Sixth.—The accepted modern method is to calculate the arch as three-hinged for dead load and erection, and then rivet up in the field, making it two-hinged for live load and temperature. It relieves the arch of much secondary stress, and causes the joints to come to their bearing. It is much the better way.

Seventh.—The arch with cantilever spans makes a pleasing structure. The economy, however, is questionable, considering the lack of rigidity of all cantilevers, and the reduction in the weight of the arch proper is slight; most of the saving in weight is due to the change of length of the side spans. It is always more economical to carry loads in tension or compression than in bending.

Eighth.—The field of the arch, for purely economical reasons, lies somewhere between 500 and 1 000 ft. The writer's experience in this line has been with small arches (250 ft.) which weigh practically the same as a simple span of the same length.

In conclusion, the writer fully realizes the vast amount of labor involved in getting these results, and the author is to be congratulated on the orderly manner in which he has presented his findings.

T. Kennard Thomson,* M. Am. Soc. C. E.—The author deserves the thanks of the Profession for the immense labor of love he has performed in making these calculations and giving engineers the benefit of the results. Mr. Thomson.

No one recognizes better than Dr. Waddell the fact that environment and special features of topography and scenery will often control the ratio of rise to span of the arch to be built, rather than the quantity of steel in the structure.

* New York City.

Mr. Thomson.

For instance, the speaker's design, Fig. 23, for a three-hinged steel arch bridge encased in concrete, to cross the Niagara River just below the Falls, has a rise of only 0.13, as compared with the author's figures of 0.20 to 0.38. In other words, the rise of this bridge will only be about 110 ft. for a span of 840 ft.

If the design were changed to give a rise of 0.25, then its height would be 210 ft., or 100 ft. higher; and in that case the floor would have to be raised 100 ft., if the deck-bridge design is to be retained, or the sides or trusses would have to extend 100 ft. or more above the floor. Neither of these changes should be allowed, in this case, as the bridge should not be so unduly conspicuous—especially in the neighborhood of the Falls; and, besides, the excess of concrete used would probably counterbalance the saving in the steel. The design as it stands is arranged to give the least possible obstruction to the view of the Falls, and has the appearance of naturally filling its proper location between the cliffs. In other words, any well-designed engineering structure will look as if it were put there by Nature, and, like a well-dressed man, will not cause a question regarding its *raison d'être*.

While speaking on the subject of economy of design the opportunity might be taken to refer to a detail of economy which applies to nearly all steel bridges, whether arches or not, but which, unfortunately, often seems to be neglected, although it is very important. It is the comparison between the efficient and excess weight of steel in a bridge. By the efficient weight is meant the weight of the plates or shapes which go to make up the necessary section to withstand the stresses. By the excess weight is meant all other steel, such as pin-plates, splice-plates, lattice-bars, pins, bolts, rivets, etc. Naturally, economy requires that the excess weights be kept as small as good design will permit.

On a small bridge, of course, there is not so much leeway as on a large one; but, for very large members, within which a painter can work, a box or circular column or strut would often be more economical than the usual web systems which are held together by lattice-bars, diaphragms, etc. When the bridge is built under a "pound price", however, there is a temptation to use the heavier sections, especially as they can be handled more easily in the shop.

The first essential in designing a column would be to make it equally strong in any direction; but this is difficult to accomplish economically when it is built up of several heavy ribs connected by latticing, etc. An economical light column can be secured by riveting an I-beam between two channels, giving a section having very little excess. This permits painting, which a small box-column does not. Where the sections are large enough to permit a man to pass through, a box or circular section would be more easily protected against rust,

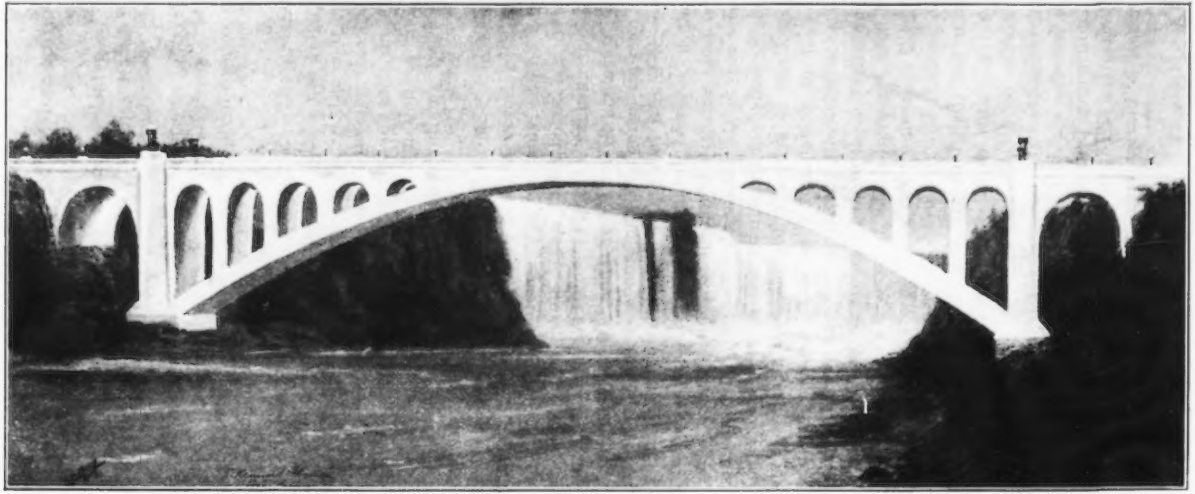

FIG. 23.—PROPOSED BRIDGE OVER THE NIAGARA RIVER NEAR THE FALLS. THREE-HINGED STEEL ARCH, ENCASED IN CONCRETE. MAIN SPAN, 840 FEET: HEIGHT ABOVE RIVER, 143 FEET.

and the saving in weight should overbalance the increase in cost of labor. Mr. Thomson.

If this rule—equal strength in any direction—had been followed in the design of the first Quebec Bridge, the disaster at that site would probably never have occurred.

The speaker knows that it would be presumptuous to try to teach Dr. Waddell anything about bridge design, but he trusts that he will be pardoned for inserting these self-evident, but often needed, remarks, for the benefit of students of bridge building.

CHARLES EVAN FOWLER,* M. AM. SOC. C. E.—The great amount of detail work involved in such a paper as this is not fully realized unless one attempts a thorough investigation of the subject. The Profession is much indebted to the author for making this systematic study of arches and for recording the results of such an extensive series of calculations. An independent examination of the subject reveals almost as wide a divergence from the author's views as there are modifications of each class of structure. Mr. Fowler.

The speaker has always believed the arch to be a splendid type of structure to "fill up a hole" or fit into a given gorge, with but little latitude for deck spans to influence true economy, if one adheres to esthetics in the best sense. This seems to be borne out by a study of the one hundred arches in Table 8 (Plate I), ranging in span from slightly less than 200 to nearly 3 000 ft. That is, such is the general conclusion with regard to deck spans, but, of course, through or half-through arches can always be designed with a real regard for economy.

The fundamental idea to be borne in mind, however, is that, even though many deck arches cannot be designed with the most economic depth, and, consequently, are not economical structures when considered alone, the total cost of the structure, including foundations, will usually be much less than that of a bridge of any other class, where there are rocky walls or a rock foundation to take up the thrust, and with slight expense for preparing the skewbacks.

Although only one hundred arches of more than 200 ft. span have been found and listed, twenty-four of which have not been actually built, arches of shorter span are probably more numerous than bridges of any other type, except perhaps simple trusses; and if stone, concrete, and reinforced concrete arch bridges are included, the number is legion. The case under consideration has to do with steel or framed arches, and the study of the list referred to has been undertaken on the assumption that each designer has had a reasonable regard for all theoretical and practical considerations, and has selected the most economical type of arch and the best theoretical proportions for it, when not hampered by unalterable conditions. The more the various structures and designs are studied, the more certain is it that there

* New York City.

Mr. Fowler.

are many flagrant departures from economy, especially in the case of the shorter spans which do not warrant a great expenditure for investigating independently the economic possibilities. The speaker has always endeavored in special cases to make such investigations, but has always believed that the economic rise was practically equivalent to the depth of a simple truss span. In other words, given a certain type of arch, the rise must be selected as nearly as possible in the same way that the depth of a truss is found, that is, deeper for the heavier and dynamic loadings. Where one-sixth rise might prove enough for producing a stiff structure for the light loading of a highway arch bridge, it would need to be increased to one-fifth, or perhaps to one-fourth, or more, for heavier loading and for railways, using the engineer's judgment for preliminary layouts to form the basis for investigations. This, therefore, does not agree fully with the author's findings. Judgment alone would have indicated that the Washington Bridge over the Harlem should have had a greater rise than 18% if in any way possible, or, the girders should have been deeper, and thus have avoided in large measure the vibration or bouncing of the structure caused by the live loads. The rise necessary to overcome this would have been much greater than the economical rise found by the author, or probably 25% of the span, or greater. The same unpleasant feature occurred in the speaker's Knoxville arched cantilever, and, in both cases, it is due largely to the inertia of a heavy paved floor, a condition which cannot be entirely overcome. The ultimate limit of economy should not be considered as the only thing to be attained; the aim should be to design a structure that shall be stiffer and therefore more lasting, without, of course, any undue increase in cost. The Alexander III Bridge, in Paris, is an even more flagrant example of a too shallow arch, and, with a rise of only one-seventeenth, the vibration, of course, is as predominant as it is lacking in arches of possibly too great rise, like the speaker's White Pass, Alaska, arch, with a rise 37.5% of the span, or the St. Croix, Minn., arch spans, with 35.5% rise.

The discussion of the subject can be taken up more understandingly by considering at this point the various types of arches that have been built (or designed), as shown by the list (Table 8, Plate I) prepared by the speaker. This list is believed to be several times more extensive than any previously compiled. The data have been checked from the original sources, as far as can be found in the Engineering Societies Library, and many errors have been corrected in data which have been in current use for some years. The various types were found to be as follows:

(*a*).—Arch ribs with no hinges, plate girders;
(*b*).—Arch ribs with no hinges, lattice ribs;
(*c*).—Arch ribs with no hinges, trussed ribs;

(*d*).—Arch ribs with one center hinge, plate girders; Mr. Fowler.
(*e*).—Arch with one center hinge, spandrel-braced;
(*f*).—Arch with two hinges, plate-girder ribs;
(*g*).—Arch with two hinges, lattice ribs;
(*h*).—Arch with two hinges, trussed ribs;
(*i*).—Arch with two hinges, spandrel-braced;
(*j*).—Arch with three hinges, plate-girder ribs;
(*k*).—Arch with three hinges, lattice ribs;
(*l*).—Arch with three hinges, trussed ribs;
(*m*).—Arch with three hinges, spandrel-braced;
(*n*).—Arch with three hinges, and fixed ends;
(*o*).—Arch with three hinges, no center depth;
(*p*).—Arch with five hinges, spandrel-braced;
(*q*).—Cantilever arches, three hinges;
(*r*).—Arched cantilevers, two hinges.

These eighteen types, of course, are only modifications of five basic types: no hinges, one hinge, two hinges, three hinges, and cantilever arches. The investigation as to the last word in economy for a given crossing, therefore, may prove to be an almost endless task, unless the engineer, from long experience, can single out two or three types which are quite sure to prove suitable. The chance of making an error therefore, would seem greater in the selection of the type, than the possibility of serious error in proportions.

It is the speaker's opinion that the economic depth can be varied 5% either way, without much exceeding the computer's most probable percentage of error in making an estimate from a stress sheet, and the variation of sectional area, which may easily total 5 per cent. This is undoubtedly borne out by a study of the author's diagrams.

The list of one hundred arches has been studied by tabulating the ratio of rise to span, as well as the depth of the ribs or arch, and an average result thus determined, which, in a great measure, is valuable as a composite of the investigation into these important features.

Plate-Girder Rib With No Hinges.—The average for the two arches of this type is only 7.2% of the span length for rise, or a ratio of $L \div R$ of 13.8; which, of course, is too shallow, and less than half the rise recommended by the speaker in Table 9. The average depth of rib at the center is only 0.9% of the span length, or about one-third of the minimum advised. In fact, the Arcole Arch, in Paris (No. 79), failed under modern traffic and had to be reinforced.

Lattice Rib With No Hinges.—The average of seventeen arches of this type is 22.6% of the span length for rise, or a ratio of $L \div R$ of 4.4; or, discarding three distinct violations of economy, 25.4%, or a ratio of 3.9, which latter value, however, is only about three-fourths of the author's average. The average percentage of L for

Mr. Fowler.

depth of rib is 3.0, but, discarding six cases where the depth is manifestly too small, the average is 3.8, or only practically one-half the value given by the author.

Plate-Girder Rib With One Hinge.—There is only one example of this type, and it agrees closely with the author's values; the percentage of rise to span length is 21.8, or a ratio of $L \div R$ of 4.6; the percentage of L for depth of rib is only 1.5, which is undoubtedly much too low, even for a plate girder.

Spandrel-Braced Arch With One Hinge.—There is only one example of this type, the design for an 1 800-ft. voussoir arch span at Quebec, and the possible rise is too low for a deck arch. The percentage of span length for rise is only 9.1, or a ratio of $L \div R$ of practically 11.0; the percentage of L for center depth is only 1.2. The location was certainly more suitable for a half-through arch of the type shown in Fig. 24, (No. 5 in Table 8, Plate I), and described later for this same crossing.

Plate-Girder Arch With Two Hinges.—There are three examples of this type, and the average percentage of rise to span is 18.7, or a ratio of 5.3; but, discarding the very shallow arch, No. 70, the average is 23.3%, or a ratio of $L \div R$ of 4.3; the average percentage of L for depth of rib is 3.2, and the maximum is only 3.8.

Lattice-Rib Arch With Two Hinges.—The average for twenty-five arches is 17.1% of the span length for rise, or a ratio of $L \div R$ of 5.8; but, discarding seven distinct violations of economy, 20.0% or a ratio of 5.0; the first slightly low value is accounted for by the seven deck arches included, of only about one-tenth rise; the average percentage of L for depth of rib is only 3.8; but, if five of the largest values are excluded, the result would be only 3.2. The average of those omitted, however, is only 6.0%, and the maximum value is 6.3%, as compared with the 7.5% recommended by the author.

Spandrel-Braced Arch With Two Hinges.—The average of the twelve cases of this type is 17.1% of the span length for rise, or a ratio of $L \div R$ of 5.8; which value is perhaps slightly too low for economy, but is accounted for by a number of deck arches with insufficient distance below grade to allow for a greater rise; the average values found by discarding the very flat arches, are 18.5% and a ratio of 5.4. The average percentage of L for center depth is 3.4, with no normal value in excess of 5.5.

Plate-Girder Rib-Arch With Three Hinges.—There are only six examples of this type, and the average percentage of rise to span length is 18.6, or a ratio of $L \div R$ of 5.4; or, discarding the two very flat arches, 23.6%, or a ratio of 4.2. The average percentage of L for depth of rib is 2.8, or, discarding the two abnormal cases, 3.3, either value being high enough for plate-girder ribs.

Mr. Fowler.

Lattice-Rib Arch With Three Hinges.—The average for fifteen arches is 20.2% of the span length for rise, or a ratio of $L \div R$ of 4.9; and, as the highest value is 27.3%, or a ratio of 3.7, this type would seem to agree more closely with the author's results. The average percentage of L for depth of rib is 3.6, for rational cases, or practically one-half the author's value; and the maximum value is only 4.8 per cent.

Spandrel-Braced Arch With Three Hinges.—The average for eighteen arches is 19.7% of the span length for rise, or a ratio of $L \div R$ of 5.1, which is only slightly less than the values recommended by the speaker in Table 9, but considerably less than those recommended by the author. The foregoing average value includes one high-deck arch in which the percentage is 35.5 and the ratio 2.8, which is the only really high-deck spandrel arch (No. 63) found recorded. The average percentage of L for center depth is 3.2, and 7.2 for the high-deck spandrel arch (No. 63).

Spandrel-Braced Cantilever Arch, Five Hinges.—The one design described in this discussion has a span of 1 670 ft. and a rise of 272 ft. The rise is 16.3% of the span, or a ratio of $L \div R$ of 6.1; the center depth is 2.1% of the span length.

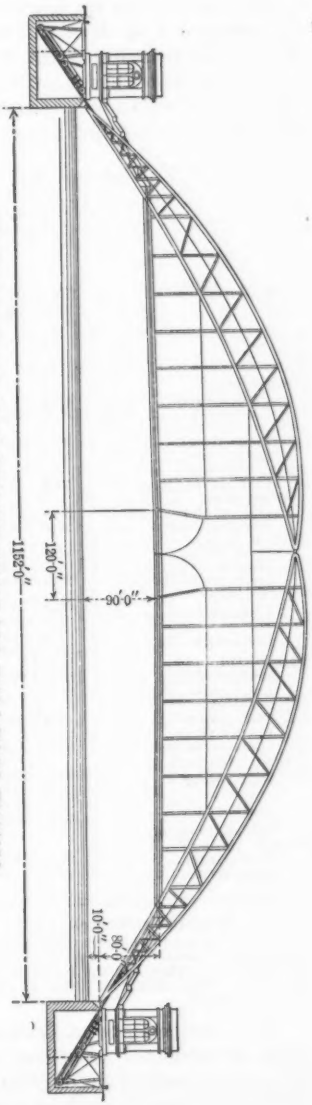

FIG. 24.

Mr. Fowler.

The average for the one hundred cases is 18.9% of span for rise, or a ratio of $L \div R$ of 5.3; the average of the author for the same cases would be 26.6 per cent. The average for the one hundred cases (18.9%) indicates how much too low is the one-seventh or 14.2% general value given by Kunz; and that the author's values are too high, especially when applied to light highway and lighter railway arches.

* First column = Waddell less 2½%, his allowable variation.

† The ratios in the last three columns are those recommended, based on a study of existing arches, Waddell's ratios, and ratios in ordinary use, giving the minimum rise for deck arches and the maximum for high deck and through arches. Not based on three middle columns. Figures in parentheses refer to the number of normal cases averaged.

The average value of depth of rib for the one hundred arches is 3.2%, as compared with 7.5% of the span length recommended by the author; and indicates that the values given by the speaker in Table 9 are more logical, or a safe basis for investigations, as it will

Mr. Fowler.

give a rib depth great enough for rational designing as well as economy. Mr. Hovey's investigations for the plate-girder arch ribs of No. 95 bear out the author's deductions for plate-girder ribs, as given in Table 9.

The Hell Gate Bridge proportions were fixed after a very careful investigation and analysis, and it is stated* by O. H. Ammann, M. Am. Soc. C. E., that:

"The weight of an arch of this type and length varies inappreciably for variations in rise between one-sixth and one-fourth of the span [or 8.3% range in rise], the absolute minimum being probably nearer the lower value [16.7%].

* * * * * * *

"The height of the trusses was decreased toward the center to 40 ft. 2§ in., or approximately one-twenty-fourth of the span length [4.1%], so as to reduce the temperature stresses, which are greatest at the center. The height of 140 ft. at the ends of the trusses was determined by the necessity for rigid portals between the end posts above the track floor. These assumptions for height resulted in the slightly reversed curve of the top chord, which produces a very pleasing sky line."

The speaker agrees with this last statement, and believes, also, that the proportions of this structure are scientific and perfectly logical.

The data by Kunz as to the proportions of steel arches are worth quoting, but are too general to be of great value. The ratio of rise to span is stated to range ordinarily from one-fourth to one-twelfth with possible extreme values of from one-half to one-fifteenth; and with an average for economy of one-seventh. (This the speaker has pointed out as being too flat, except possibly for very light highway bridges.) Kunz states that the center depth should range from one-sixtieth to one-fifteenth (or 1.7 to 6.6%), and he recommends for two-hinged, spandrel-braced arches, with parallel chords, from one-twenty-fifth to one-twentieth (or from 4.0 to 5.0%, which accords with the speaker's views); crescent ribs from one-eighteenth to one-fifteenth (or from 5.6 to 6.7%, which the speaker has pointed out to be very extreme values); with spandrel-braced arches, where the height is limited, the center depth may be as small as one-fortieth (2.5%), but the center panels should have solid webs. The foregoing may be reduced from 25 to 40% for highway bridges. Kunz also states that the depth of plate-girder ribs should be from one-sixtieth to one-fortieth (from 1.7 to 2.5%, which are certainly minimum values); and that the suspended span of cantilever arches should be from one-half to five-eighths of the side span.

Conclusions.—The conclusions reached by the speaker, from the foregoing average values, the author's values, and a study of the

* In his paper entitled "The Hell Gate Arch Bridge and Approaches of the New York Connecting Railroad Over the East River in New York City", *Transactions*, Am. Soc. C. E., Vol. LXXXII, p. 852.

Mr. Fowler.

individual designs in detail, are that the following conditions should be observed:

Where the possible rise below grade would make the arch too flat for rigidity, as in numerous cases listed, notably the Alexander III Bridge, the Washington Bridge, the St. John Bridge in Canada, and the design for an 1 800-ft. arch at Quebec by Worthington, then a half-through type of arch would be preferable. Although the vibrations from the live load are not all due to the small rise, as has been shown in truss spans of extra depth built by the speaker, where the bouncing could only be attributed to the inertia of a heavy, paved floor, the greater rise recommended is certainly advisable.

Where there is a greater depth below grade, than is required for economical rise, the economy of the structure is but little changed by making the rise proportionately great, leaving no more, in any case, than room above the crown of the arch for a distributing truss, if it is to be used, and not carrying the roadway directly by long posts, which are unsightly when they extend above the top of the arch rib. The designers of the Viaur, Cleveland, Luiz I, Mungsten, Garabit, Pia Maria, Kornhaus, St. Croix, White Pass, Blauw-Krantz, Youngstown, Fern Hollow, Namti, and Surprise Creek Arches evidently found this method of design most artistic, and fairly economical, or they would not have used such proportions. The speaker has in mind no actual cases which would indicate a contrary view.

Wherever possible the rise should be greater than indicated by theory or ordinary practice, especially in the case of railway arches or those for heavy highway loads, and it is found that twenty-four of the arches in Table 8 (Plate I), have a rise of practically 25.0% or greater, and eight of these have a rise greater than 30.0 per cent. The study of individual cases indicates that the depth should seldom be less than 20.0%, and should preferably be 25.0% or greater, in the interests of stiffness and consequently longer life of the structures carrying the heavier loadings.

Where the best bridge is desired, that is, the one with the greatest ultimate economy, and not the cheapest in first cost, it will usually be found economical, and more artistic with a deck structure, to build it with a rise greater than 25.0%, and often up to 40.0% or greater, when there is room below grade; or even for a half-through arch when it would not prove to be top heavy.

Where the possible rise is materially less than 17.0% for heavy loading, some other type than a deck arch should be used, or the idea of an arch should be abandoned and a structure of an entirely different type designed.

The depth of rib, or center depth, as recommended by the author, would seem to be excessive; and, for arch ribs, the center or quarter depth should only be from 3.0 to 4.0% of the span length, except in

the case of solid ribs, where the depth might be as small as 2.5%, but never less than 2.0%, unless for some unavoidable reason, and greater than 2.5% for spans of small rise. Mr. Fowler.

The end depth of ribs without hinges, of course, must be greater than at the center or crown, as required by the stresses, but, for appearances, never less than one and one-half times the center depth, and usually not less than two and one-half times. The greatest ratio is four times, as in the great Mungsten, no-hinge, lattice-rib.

The center depth of spandrel-braced arches has varied all the way from 0.0 to 8.5%, but a depth of about 4.0% would seem to be economical and artistic, and a depth as great as 7.0 or 8.0% would often be decidedly displeasing.

The center depth of three-hinged ribs is perhaps more pleasing when not less than the greatest depth of the rib, but such a design is not the most economical, as will be shown later.

The center hinge in a spandrel-braced arch has been placed almost always in the lower chord, and this is a much better location, especially with respect to detailing the structure.

The list, Table 8 (Plate I), in which 74% of the structures are deck arches, and which is as complete as the data in the Engineering Societies Library afford, shows that for steel arches from about 200 ft. to 3 000 ft. span, there have been designed and built of the no-hinge type 19.0%; of the one-hinge type 2.0%; of the two-hinge type 40.0%; of the three-hinge type 39.0%; and, of all these, 71% have been of the arch-rib type and only 29% of the spandrel-braced type.

Therefore it might be concluded that designers have found the arch rib much more economical as well as more artistic than the spandrel-braced arch, and the types with no hinges and one hinge less economical than those with two and three hinges, although this quite certainly has been due, to some extent, to an unwarranted prejudice against wholly statically indeterminate structures. From the tabulation and other published data, the practical economy of the two-hinged and three-hinged types may be considered as equal.

The findings of M. A. Howe, M. Am. Soc. C. E., as to the no-hinge type being the most economical, and the two-hinge type next in economy, agrees with the speaker's experience; and, as to the relative economy of the two-hinged and three-hinged types, this is borne out by the author and by the investigations* of C. W. Hudson, M. Am. Soc. C. E., the arches being of the spandrel-braced type, of 20.0% rise and 3.0% center depth, having a span of 200 ft., and designed for a paved highway. The weight of the two-hinged arch was found to be 109 000 lb. and of the three-hinged arch 115 000 lb., or a saving of 5.5% in favor of the two-hinged structure. H. S. Jacoby, Assoc.

* *Transactions*, Am. Soc. C. E., Vol. XLIII, p. 20.

Mr. Fowler.

Am. Soc. C. E., gives a comparison* of two-hinged and three-hinged designs for the 550-ft. Niagara Arch, and states that the three-hinged arch showed a saving of only 0.84% over the two-hinged type. The investigation of an arch, three-hinged for dead load and two-hinged for live load, showed 4.2% greater weight than the regular two-hinged type.

The speaker's investigations for this discussion have convinced him that the three-hinged, parabolic, lattice-rib arch, as shown in Fig. 24, is the most economical type of any given in Table 8 (Plate I), and it is certainly worth investigating for any long and important span. Table 8 gives the economical proportions for an arch of this type, for Nos. 3, 5, 6, 7, and 8. It indicates that the economical rise for heavy loads is from 19.3 to 23.5% of the span length, and the economical maximum depth of the rib as only from 4.3 to 4.8% of the span length, although the exact depth of rib is determined automatically for each case by the calculations. The development of this type was due to Mr. Max am Ende, the English engineer who designed the Blauw-Krantz Arch, South Africa (No. 86). The type was evidently first proposed in 1892 for the Thames River at London, just below the Tower Bridge.† The outline of the arch ribs is of most interest in this discussion, but the general scheme of this 1 152-ft. arch span is worthy of brief description. The roadway has a clearance of 90 ft. above the water and 80 ft. above the grade on shore, this difference of elevation being overcome by platforms operated on inclined tracks to elevate vehicle traffic to the level of the bridge roadway. All ordinary vessels could pass under the roadway, but, for vessels with tall masts or funnels, the double bascule opening of 120 ft. is provided. As the theory of this parabolic arch-rib structure has been fully developed‡ space will not be taken here, except to explain that the top flange of each half rib has the form of the curve of pressures for that half loaded, and the bottom flange has the form of the curve of pressures for that half unloaded; thus, both flanges are normally always in compression. All will remember the old bowstring truss, also the King and Massillon Arches, each of which closely approximated the outline of the moment curve, and was theoretically of the lightest weight for a simple span. Engineers still endeavor to make truss outlines, for economy, conform as closely as possible to the form of the curves of moments, and, therefore, it is not surprising that this parabolic rib arch should prove economical. It is in reality the Fidler truss for a suspension bridge reversed. Mr. am Ende has also proposed a suspension bridge of this type for the Straits of Messina, of 3 280-ft. span, which, as far as the

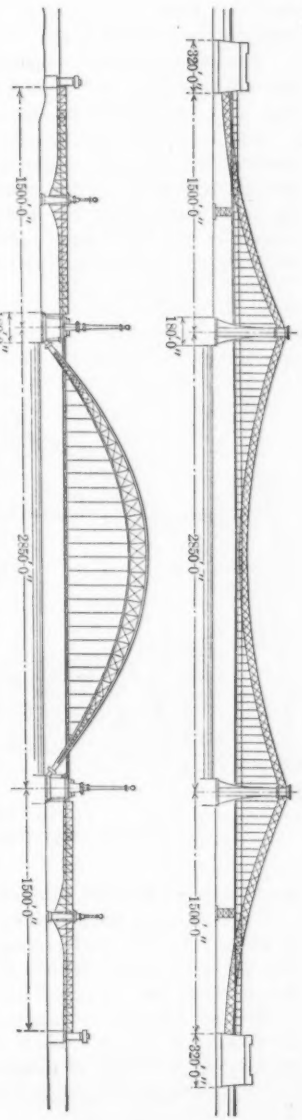
* Discussion of Mr. Hudson's paper in *Transactions*, Am. Soc. C. E., Vol. XLIII, p. 31.

† This bridge is fully described in *The Engineer*, March 18th, 1892.

‡ *The Engineer*, April 14th and May 19th, 1893.

Mr. Fowler.

speaker knows, is the longest span of any kind that any one has had the temerity to propose seriously. Among the designs listed in Table 8 (Plate I), is one for the Firth of Forth of two 1 650-ft. spans, for which the weight estimated is 24 942 long tons (or 10 763 long tons in one arch span), as compared with the total of 51 000 long tons for the structure actually built. The weight of this arch design can only be approximate, but the formulas for the weights of the various portions of such spans are Mr. am Ende's Equations Nos. 10, 12, 13, 14, 23, 26, 34, and 35,* and would form a valuable basis for investigating this type. The other bridges proposed were for Quebec, of 1 600-ft. span, with a weight of 11 714 long tons (or 9 264 long tons for one arch span); for Sydney, Australia, of a 1 600-ft. span, with a weight of 11 786 long tons; and for the Bosphorus, in Turkey, a double-track bridge with a 1 240-ft. main span weighing 5 172 long tons, having a total estimated weight of only 6 072 long tons, as compared with 9 952 tons for a cantilever design, the live load being 5 600 lb. per lin. ft. of bridge. The speaker considers any type of structure which can make such a supposedly favorable showing to be worthy of investigation;



Proposed Modification

PROPOSED DESIGNS FOR A BRIDGE OVER THE NORTH RIVER, NEW YORK.

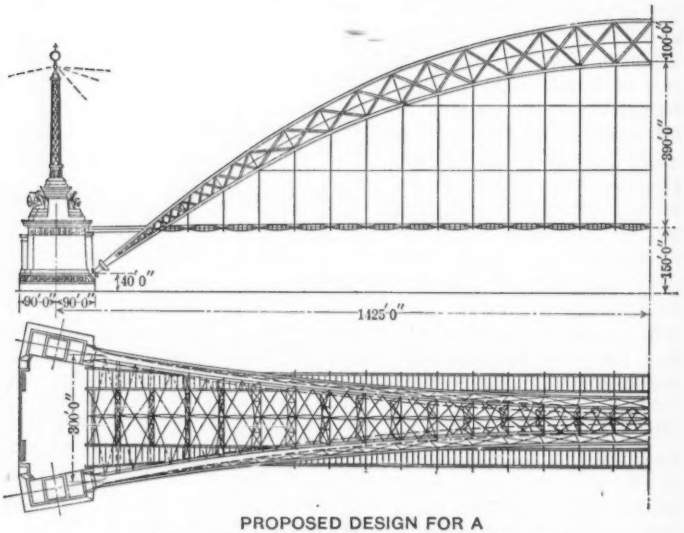
FIG. 25.

* *The Engineer*, April 14th, 1893.

Mr. Fowler.

and this type, moreover, is much more graceful and pleasing than many other arch-rib types.

The same engineer proposed an arch span (No. 1) of 2 850 ft. for the Hudson River at New York, Figs. 25 and 26.* This, however, was a two-hinged sickle-shaped lattice rib of 440 ft. rise, which is only 15.5% of the span length, and indicates how top-heavy a through-arch of greater rise might become. The center depth of the rib, though only 3.5% of the span length, is 100 ft., and calls attention to the impossibility of using the 7.5% proposed by the author, especially for the longer spans. The statement of the author that 3 540 ft. is the maximum limit for an arch span, with present materials,



PROPOSED DESIGN FOR A
BRIDGE OVER THE NORTH RIVER, NEW YORK.
FIG. 26.

would seem to be open to question, in view of such an unprecedented arch span having been quite carefully worked out by Mr. am Ende in 1889. The fact that proper foundations could not be secured, and that the comparisons with a suspension span are erroneous, does not detract from the value of his study and investigations.

The arch with five hinges, referred to in the classification, has not been included in Table 8 (Plate I), as it is a special type which, however, is deserving of mention. The design by Charles Bender for

* Fully described in *The Engineer*, May 17th, 1899.

two 1 670-ft. five-hinged arches for the Forth Bridge has been described at length by him.* He states that the weight was calculated twice independently with only 1% difference in the two estimates, so that the weight of 24 260 tons for the 5 320 ft. of bridge may be considered reasonably exact, to be compared with the 42 000 tons for the same length of that bridge, as actually built, and with the weight of 24 942 tons of the more logical three-hinged parabolic arch design (No. 3) of Mr. am Ende. The five-hinged design has two cantilever arms, each of 349 ft., with the arch chord pin-bearing at the springing or abutment, and supporting a three-hinged, spandrel-braced closing or suspended span of 1 002 ft. This is similar to the arrangement of the three-hinged fixed-end arches, Nos. 16 and 44, and is evidently worth investigating for long spans. The rise of the whole arch is 272.0 ft., or 16.3%, and 6.1 ratio of $L \div R$; the end depth is 278.0 ft., and the center depth 35.0 ft. or 2.1% of the span length. These figures denote a very well proportioned structure. Table 10 shows the proportions of all the designs for the Forth Bridge. Mr. Fowler.

† Simply included as a comparison of arched chord.

The arches, Nos. 81, 82, 83, and 88, in Table 8 (Plate I), are selected from those designed or built by the speaker, and are included in the list because all are quite striking, although they are not extremely long spans. The 255-ft. double-track railway arch at Spokane (No. 81, Fig. 27), as far as the speaker knows, is the longest spandrel-braced arch ever built with timber compression members. The design was made when C. T. Morris, M. Am. Soc. C. E., now of the Ohio State University, was Assistant Chief Engineer for the speaker, and it was planned to substitute steel compression members later for the two 10 by 24-in. arch timbers, and the other posts and struts in the structure, as the floor-beams, stringers, and bars were of steel. The erection of the arch presented no unusual difficulties, except that the erection superintendent failed to discover that the pin castings were not planed to the proper distance from the pin center, and the arch chord was consequently too long. This made the rise greater than intended (and the arch stronger), so permission was obtained

* "Principles of Economy in the Design of Metallic Bridges", New York, 1885.

Mr. Fowler.

to make all the diagonals turnbuckle members, and the extra camber was framed out in the ties.

The Knoxville arched cantilever, built by the speaker in 1896 (No. 68, Fig. 28), has been included as belonging to the cantilever arch type, and though possessing the desired artistic features, is possibly not as stiff under loads as even an ordinary cantilever. The spans were not made true arches after erection, on account of the great height of the piers.

The first design for the Youngstown Arch (No. 88, Fig. 29) was of the type of arch with cantilever end spans (No. 89) and as shown by the author in Fig. 14, but it was not found to be as economical as the two-hinged plate-girder arch as built. The stress sheets were made under the speaker's direction by E. M. Scofield, M. Am. Soc. C. E., then Principal Assistant Engineer of the Youngstown Bridge Company, and the calculations were made by Cain's graphic method. When checking up the stress sheets before construction, the late Professor A. H. Heller, then Assistant Chief Engineer, used Howe's analytical method, and found a practical agreement. The dead-load moment was 972 000 ft-lb., the live-load moment was 2 054 000 ft-lb., and the temperature moment 368 000 ft-lb. The structure had a paved deck, 60 ft. wide, the dead load being 6 200 and the live load 4 720 lb. per lin. ft. The load was carried to the arch ribs, 8 ft. deep, by posts supporting a lattice distributing truss, 10.5 ft. deep. The sub-trussing in the 165.5-ft. approach spans was made of the same depth, for harmony, and these spans were square-ended, 30 ft. deep, to give a proper backing to the arch, for appearance. This investigation indicates that all proportions of this structure were correctly determined. The speaker has found no other two-hinged plate-girder arches of more than 200 ft. span, except the Washington Bridge over the Harlem, and the Mayence design (No. 70).

The outline of the Switch-Back Arch on the White Pass and Yukon Railway, in Alaska (No. 83, Fig. 30) was made by the late H. S. Wood, M. Am. Soc. C. E., but, owing to a change in dimensions, was re-designed by the speaker before constructing it. The design is believed to be much more economical than a true or curved arch with long vertical posts, and, moreover, it was much cheaper to erect. It was designed for two 96-ton consolidation locomotives, with a train load of 2 700 lb. per lin. ft. The outline and graphics are shown on Fig. 31. The arches at Blauw-Krantz (No. 86) and at Namti Gorge, in China (No. 98), are of the same general type, the first named being what might be termed a no-hinged, rectangular arch, and the latter a three-hinged, trussed-rafter arch.

The subject is an absorbing one, and a volume could profitably be written describing the striking features of the arches on the list, but space prevents any further discussion, except to call attention

SWITCHBACK ARCH BRIDGE, WHITE PASS & YUKON RY., ALASKA.

FIG. 31.

Mr. Fowler. to the two three-hinged, fixed-end arches: the 626.9-ft. span at Vilaine, France (No. 16), and the 460-ft. span of the Austerlitz Bridge, in Paris (No. 44). They are the two most striking designs listed, and the latter proves how easily such a flat arch as the Alexander III Bridge could have been avoided.

The speaker's final words must call attention to the fact that the proportions fixed by him are average values for both short and long spans, and, though only small loss would result from their blind application to short spans—and ribs of too great depth would not be very unsightly for short spans—it is perceived, from a study of the longer arches, that it is often desirable to use a comparatively small rise, both as a measure of economy and as a prevention of top heaviness, and a comparatively small depth of rib, as one which is too deep would be uneconomical, unwieldy, and unsightly.

The conditions under which the load is applied to the arch rib may be a factor of economy, especially when a distributing truss is used and a considerable portion of the load is carried directly to the abutments. Then, too, the character of the steel will be a factor in fixing the economic proportions; and the entire problem of the design of large arches must be approached with an open mind, and a mind in full working order, to solve the particular case in hand.

Mr. Farr. W. B. Farr,* Esq. (by letter).—Due to the disadvantage of having only an abbreviated form of Dr. Waddell's paper, which abbreviation, it is stated, was necessitated by economy in publication owing to present-day conditions due to the war, and also to the fact that the sheets of graphic stress calculations, diagrams of stresses, and sections of metal, etc., and other particulars necessary for the full consideration of the paper, are not accessible, it is only possible for the writer to give the subject general consideration.

There can be no question that an arch bridge, whether the arch be of masonry or of metal, is more esthetic and pleasing to the eye than any form of girder or truss bridge with the usually straight bottom boom and rectilinear opening; though it cannot be denied that some bridges with trusses of large span by their very magnitude are impressive to the ordinary observer and quite beautiful to the trained eye of the engineer who alone can thoroughly understand and appreciate them.

A number of the large truss bridges erected in recent years in the United States are imposing and have the beauty of fitness to the eye of any one able to appreciate their design and construction. Any one who has stood on the track platform of the large bridge (the largest still of its type in existence) over the Firth of Forth, near Edinburgh, Scotland, and looked down the long vista of bracings,

* Chester, England.

intersecting in every direction, will be bound to admit that the sight is very imposing and beautiful, although the side elevation of the bridge, if imposing in its magnitude, cannot be said, even by one with a trained eye, to be a beautiful structure; it is, in fact, quite unnecessarily ugly. Mr. Farr.

Unfortunately, in this utilitarian age, the point as to whether or not a bridge will be esthetic, does not decide the matter, for the engineer is bound to consider his design from the point of view of cost, and whatever type of truss or arch, etc., is decided on, must be in most cases such that the bridge can be constructed at a minimum cost. Of course, there are exceptions, but the position stated usually decides the matter.

Dr. Waddell's paper is a most valuable contribution to the information available for the use of an engineer called on to decide not only the question of arch *versus* truss in his design for a new bridge, but also the question of the type of arch, whether the ribs should be of the two- or three-hinged type and with or without spandrel bracing or without hinges and with fixed ends. Lists of weights, etc., are given for all these types and will be found to be very useful, the information available in the literature of the Profession on the subject being very meager. The economic ratio of rise to span, economic depth of rib, and location of the crown hinge in three-hinged arches are all fully discussed, and valuable particulars are given.

The tables, diagrams, etc., even as given in the abbreviated form, are interesting as closely agreeing with the results of similar problems worked out independently, but not in such detail, by other engineers. It is not quite clear why Dr. Waddell, in Tables 4 and 6, gives the total weight of metal in pounds per linear foot "per side" for ribs and lateral system, while, in Table 5, he gives it in pounds per linear foot "of structure"—which appears to be a more desirable manner of stating it than "per side"—and perhaps he will be good enough to give some explanation of the matter.

The three-hinged arch with spandrel bracing will probably be chosen in most cases, owing to the stresses and reactions being determinate and ascertainable more readily and accurately than in the case of the two-hinged type or the type with fixed ends, because in these cases before an engineer can attempt to determine the stresses and reactions, he must make certain assumptions as to the elasticity of the superstructure and of the abutments, which may be sufficiently correct in his own estimation, but not so in the judgment of others, and which hypothesis cannot be absolutely demonstrated to be correct. In the case of the three-hinged arch, however, the locus of the curve of the center of pressure being definitely known at the three-hinged points, it is, therefore, definitely known at all other points

Mr. Farr.

in the rib. Stresses in the superstructure due to variations of temperature, are eliminated in the three-hinged type, and these conditions will quite overbalance the defects due to the slight want of stiffness and greater vibrations under a moving load. It is quite inconceivable that a railway train would be allowed to cross such a structure at a high rate of speed, while in a highway bridge the vibration would be quite negligible.

The economy in the weight of metal in the arch over the simple truss appears, from the information in the paper, to commence at spans of more than 1 000 ft., but no comparison with the continuous truss of varying depth (of which the Forth Bridge is an example) is given. In bridges of several spans of more than 700 ft., a continuous truss of this type will be found to be much lighter in weight than any other truss or arch.

As it is only in the larger spans of more than 1 000 ft. that any economy in weight is shown over even a simple truss, and as the span at which the arch will come out lighter in weight than the continuous truss will be very much more than 1 000 ft., and as opportunities to construct such bridges are, especially in the Old World, of rare occurrence and not likely to enter into the experience of any but a few engineers and those in the highest ranks of the Profession, consequently, the average engineer is not likely to have an opportunity of constructing such a structure and can only as, in the writer's case, take an academic interest in the problems so ably dealt with by Dr. Waddell, to whom the thanks of the Profession both in the United States and England are due. The labor involved in the preparation of the paper and its attendant diagrams and tables must have been enormous.

In deciding on the type of bridge, in addition to the actual weights of metal in the superstructure, there is the question of abutments, nature of foundations, transportation and erection, and cost of maintenance and painting (which are too often overlooked in making an estimate of cost, as this work of maintenance, etc., frequently falls on shoulders other than those of the man designing the structure). The weight of the bearings at the ends of the three-hinged arch will vary according to the weight on them and, also requires to be taken into account, as by reason of the difficulties of, and the care required in, fixing, they may cost a considerable amount. Arches in metal are not suitable for a series of spans in a long and lofty viaduct, as it would not be possible to construct them satisfactorily on high braced or masonry piers, on account of the unbalanced thrust due to advancing moving loads over the spans. Construction of this type in such positions would probably never be seriously considered, but such viaducts are eminently suitable for crossing river gorges of comparatively narrow widths, with rocky sides forming suitable abutments

to take the horizontal thrust of the arches—such as those already erected at Niagara, or Victoria Falls on the Zambesi, over the River Douro, at Oporto, Spain, and the Garabit Viaduct in France—where it is easy to erect the arch ribs by tying them back to temporary abutments during erection, and where it would be difficult and expensive to erect a simple truss bridge. Mr. Farr.

HORATIO P. VAN CLEVE,* ESQ.†—Some one has said, "Genius is the capacity for doing work", and the speaker has had the truth of this assertion very forcibly impressed on him in reading this paper. In his preface to "Bridge Engineering" the author says that it was due to the World War, and the consequent stagnation in bridgework, that the writing of that treatise was made possible. It is probably no less true that the work on this paper could hardly have been done during the stress of the author's usual professional activity. Mr. Van Cleve.

Some idea of the extent of the calculations incident to the preparation of the paper may be gathered from the statement—appearing as a foot-note under Problem No. 1—that seven designs were made for each of two loadings and presumably three types of rib, forty-two in all, in order to furnish data for that problem. Some short-cuts were undoubtedly made use of, but a casual consideration of the number of cases treated leaves little to be imagined regarding the extent of the labor involved.

The author's method of attacking the problems, namely, that of calculating quantities from actual designs, although more tedious, is far more practical than any wholly theoretical treatment, owing to the large number of variables involved. The latter method of investigation might perhaps have been pursued, but it would probably be more valuable as an exercise for the mathematical gymnast than as a working basis for the practical designer.

The form of the paper, although of secondary importance, deserves perhaps some attention at the hands of the critic. The speaker wishes to suggest that the matter presented would be more easily followed, and would be more convenient for reference purposes, if each natural division were prefaced by a re-statement of the problem to be solved, and, similarly, if appropriate notations were used for marking the subdivisions of the problems.

The speaker is interested in the author's proposal, in Problem No. 6, to make the arch rib three-hinged for dead load, and two-hinged for live load. It appears that a slight saving of metal would result from this expedient. To place a field splice across the crown-hinge would undoubtedly be possible, but, in the speaker's opinion, would rarely be justifiable, owing to the quantity of splice metal required, and the expense of the field drilling.

* New York City.

† Now M. Am. Soc. C. E.

Mr. Van Cleve.

The chief value of the paper, as the speaker sees it, lies in the fact that it forms a basis of operations in steel arch calculations, guiding the designer's judgment, and thereby eliminating much of the cut-and-try work often resorted to, only to be discarded. In filling this much felt want, it will, no doubt, fully accomplish the author's purpose.

Mr. Jacoby.

HENRY S. JACOBY,* ASSOC. AM. SOC. C. E. (by letter).—The author deserves the hearty appreciation of the Profession for offering for publication the results of his elaborate investigations on certain economic relations of steel arch bridges. Only those who have undertaken similar work can comprehend what a vast amount of labor was involved.

Since the construction of the two arch bridges over the Niagara River, completed in 1897 and 1898, respectively, steel arches have been a subject for original investigation by many graduate students and some undergraduates in the Bridge Department of Cornell University. Brief statements of some of the most important results have been published.†

In order that the results might have more than an academic interest, actual designs have been used as the basis for comparative designs made under various conditions, in order to determine the relative weights and deflections of steel arches of different types.

A comparative study of different steel arch bridges actually built may not permit definite conclusions to be drawn in regard to economic design, because the loading, unit stresses, and other items of the specifications differ materially, and there are variations likewise in the form and proportions of the arches, and in the type and weight of floor systems. It is instructive, however, to consider certain facts related to past practice in the construction of steel arch bridges.

Eleven years ago Mr. C. H. Mallison compiled a table of about eighty American bridges containing metallic arches, with spans varying from 33 to 840 ft. About 85% were highway bridges. A study of this list shows that the number of arch bridges with three hinges is very nearly equal to the sum of those containing two or no hinges. In those with three hinges there are from three to four times as many having open webs as solid webs, and, for those without hinges, this relation is reversed in nearly the same proportion. Of the arches with two hinges, the number having open webs is more than

An article on an investigation of comparative deflections of steel arch ribs with three, two, and no hinges, by Mr. Phoo Hwa Chen, *Cornell Civil Engineer*, Vol. XXVI (Feb., Mar., 1918), pp. 184, 229.

Mr. Jacoby.

two-thirds as large as those with solid webs. Of the arches having open webs, more than three-fourths of the three-hinged arches are spandrel-braced, but only one-half of the two-hinged arches are of that construction. It would be interesting to know whether these general relations have been changed materially by the bridges built during the past decade.

Of the eighty bridges referred to, 25% have a span of less than 100 ft., 35% from 100 to 200 ft., about 20% from 200 to 300 ft., and about 20% have a span of more than 300 ft. The large number of short spans is due to the fact that steel arches have been used in parks and in cities where esthetic rather than economic reasons governed the choice of the type. In general, as the spans decrease in length, the use of solid webs increases.

Mr. Mallison found the proportions to be as given in Table 11, all values being expressed as percentages.

TABLE 11.

No. of hinges.	Character of web.	Ratio of Rise to Span.			Ratio of Crown Depth to Span.		
		Max.	Min.	Average.	Max.	Min.	Average.
3	Open.....	37.5	9.5	18.3	6.0	1.3	3.1
3	Solid.....	30.3	8.2	15.3	5.1	1.3	3.2
2	Open.....	27.8	7.1	17.6	6.7	2.2	3.7
2	Solid.....	28.6	8.0	14.1	4.2	1.9	2.7
0	.....	21.7	7.0	12.2	6.1	1.4	2.8

As the maximum values for the rise range from nearly four to about three times the corresponding minimum values, the effect of local conditions at the sites is indicated clearly. It will be noticed that the average values are highest for arches with three hinges and lowest for those without hinges.

The great range in crown depth from maximum to minimum seems hardly to be justified, either by economic considerations or local conditions, and serves to show the need for such investigations as have been made by Dr. Waddell.

On comparing the values in Table 11 with those determined by the author on the basis of economy only, it appears as if the latter values may serve a useful purpose as maximum limits when making a design for any particular locality.

Slightly more three-hinged arches have parabolic chords or axes than circular ones, but, for two-hinged arches, this relation is reversed. Nearly all the arches without hinges have circular axes or chords. Apart from the curves named, the straight line, hyperbola, and ellipse are used in only a few exceptional cases. The modern tendency is to increase the use of the parabola.

Mr. Jacoby.

Eighteen years ago, in discussing a paper on spandrel-braced arches, by C. W. Hudson,* M. Am. Soc. C. E., the writer recommended that two-hinged arches be designed and erected so that the dead-load stresses would be distributed as in three-hinged arches, and the live-load, impact, and temperature stresses as in two-hinged arches. This is accomplished by closing the arch with a temporary hinge and afterward transforming it into a two-hinged arch, at the proper temperature, when the structure is otherwise complete. In a spandrel-braced arch, this can be done by inserting the final member, without stress, at the mean temperature, and by riveting the connecting plates where the temporary hinge is located. By thus eliminating stresses due to inaccuracies in shop work, and due to erection, a higher degree of economy may be secured. It is gratifying to observe that this method has been used in practice in a number of notable examples. In some cases, however, the transformation to the two-hinged type was made before the floor system was put in place.

A study was made by Mr. R. W. Parkhurst to ascertain the influence of the position of the crown-hinge on the deflections of a three-hinged, spandrel-braced arch. For this purpose he used special designs based on the proportions and loads of the Niagara Arch Bridge, having a span of 550 ft. There are sixteen panels in the span. For convenience, let *B*, *I*, and *T* represent the three cases when the crown hinge is in the bottom chord, intermediate between the chords, and in the top chord, respectively. At Panel point 4, the quarter point of the span, the deflections under full live load are found to be 22 and 72% greater for Cases *I* and *T* than for Case *B*. At Panel point 6, the deflection for Case *I* is very slightly less and for Case *T* slightly greater than for Case *B*. At Panel point 8, the center of the span, the deflections for Cases *I* and *T* are, respectively, 40 and 55% less than that for Case *B*. The best form of deflection curve is given when the crown-hinge is between the top and bottom chords.

For a concentrated load placed at the center of the span, the deflections for Case *I* are intermediate between those of Cases *T* and *B* at all panel points, the greatest deflections being those of Case *B*. At Panel point 8 the deflections for Cases *I* and *T* are, respectively, 27 and 42% less than that for Case *B*.

When a concentrated load is placed at Panel point 4, the quarter point of the span, the differences between the deflections throughout the span are comparatively small. At the load, the deflection for Case *I* is almost midway between those of Cases *B* and *T*, that for Case *T* being the largest. At Panel point 8, the center of the span, the deflection is downward for Case *B* and upward for Cases *I* and *T*. At Panel point 12, the third quarter point of the span, all the deflections are upward, that of Case *I* being the largest, and that of Case *T* being the least.

* *Transactions*, Am. Soc. C. E., Vol. XLIII (1900), p. 34.

H. S. SALES,* ESQ. (by letter).—It would be difficult to over-estimate the value of the information given in this paper. To the engineer who is first confronted with the problem of designing a steel arch, innumerable difficulties present themselves; and these have to be studied and solved *ab initio*. In a country like India, where steel arch bridges are seldom, if ever, used, it is unlikely that the engineer will be able to obtain much assistance in designing one, either by the advice of his colleagues, or by reference to recorded experience. One of the first questions he will ask is whether or not his preliminary layout is economical. It would be impossible to arrive at a decision on this vital point unless he had at his disposal sufficient time to work out a considerable number of skeleton designs, which is extremely unlikely. The labor involved can be better imagined than described in detail, as it is well known that arch calculations, compared with simple truss calculations, are extremely intricate; and it requires considerable practice to gain any facility in the work. With the aid of Dr. Waddell's notes and charts, the engineer's labors, however, will be lightened considerably, and, in fact, to such an extent that he will be able to begin the detailed design of an arch bridge systematically, provided he has had experience in steel structural work, and has a few type designs representing modern practice to which he can refer. Dr. Waddell remarks: Mr. Sales.

"Occasionally, an American bridge engineer builds a steel-arch structure; but usually simple-truss spans are adopted because their approximate weights and their economics are on record."

If this applies to America, it may be supposed that the same conditions prevail in India. The reason is obviously due to the circumstances under which engineers in India are necessarily placed. As mentioned previously, the beginning of steel arch design, leaving out the question of experience, necessitates an amount of study and time which the engineer cannot usually devote to the subject. Most engineers realize this, and would not willingly accept the task of designing an arch bridge unless sufficient time was available for carrying out the preliminary work thoroughly and systematically. Any information, therefore, which will result in a reduction of labor connected with the complicated preliminary calculations will be most gratefully received, and the thanks of the Profession in India are due to the author for his valuable paper, and the assistance which is to be derived by studying it.

The economy of steel arch bridges is established beyond question. The price of steel has gone up by leaps and bounds, and it may be safely assumed that finished structural steelwork cannot, in the near future, be obtained for much under Rs. 300 per ton. Within the next few years, therefore, it is reasonable to suppose that proposals may

* Bridge Engr., North-Western Ry. (State), Simla, India.

Mr. Sales.

be put forward for steel arch bridges, when conditions justify their use. It is much to be regretted that space could not be found to publish with the paper the graphic calculations of stresses, diagrams of stresses and sections, and tabulated estimates of metal, etc. The information would be valuable and instructive as examples of preliminary calculations and designs for reference. As an instance in support of this statement, take the extreme case of a hingeless steel arch: The estimation of the stresses in structures of this kind is anything but straightforward work, except, perhaps, by experts. Quantities have to be assumed tentatively, as, for example, the moment of inertia of the rib at various points. Hence correct judgment plays a very important part in the preliminary investigations; and, without it, the uninitiated is likely to waste a lot of time before he begins the actual design of the structure. Also, it is beyond question that the expert discovers for himself methods by which close approximations can be made, thus reducing to a minimum the trial-and-error part of the work. It is probable that the unpublished matter contains many shortcuts of the kind just mentioned, and that the paper would be more valuable if this part of the investigation work had been included.

The writer thinks that few experts in the design of steel arch bridges are to be found in India. The author himself draws attention to the need for special knowledge of this branch of bridge engineering, and even goes so far as to say that comparatively few structures of this kind have been built in America. There are certainly very few, if any, steel arch railway bridges in India. It would seem, therefore, that the author has undertaken the task of educating engineers in this particular branch of the profession; and the writer regards this paper as a successful effort in this direction. His only regret is that it could easily have been more complete. Nevertheless, it is hoped that, judging by past experience, the author will find time to write a treatise on arch bridges, and include in it all the diagrams and preliminary work for which space could not be found in his paper. These remarks lead to the consideration of an aspect of steel arch bridge design which, in the early days, was considerably neglected, but which, nevertheless, now seems to be receiving the attention it deserves. The writer refers to the peculiar knowledge possessed by the expert, namely, that which is concerned with the possible lines on which steel arch bridges can develop by alteration of type or shape of structure. The important question which he so frequently asks himself is: Is bridge design wholly science; or should it be largely an art? An enthusiast in any constructive science, the engineer included, will use all the means at his disposal to effect his object, whether these means consist in mechanical skill or the application of mathematical knowledge. In steel bridgework both are essential, and perhaps in some work, notably the arch bridge, mathematics plays the

most important part. Unfortunately, mathematics is regarded by many as the beginning and end of all bridge design; so that many engineers have, at last, been deterred from advancing on certain lines of progress because they felt that they could not undertake the enormous amount of computation work necessary before the actual scheming could be put in hand. To these the actual design had necessarily to occupy a secondary place which could not be approached without the mathematical knowledge required to complete the preliminary work. If, therefore, the mathematics of steel arch bridges can be presented in such a way that it constitutes a well-made tool from which further operations can begin, then the engineer is at once raised to a new level, and a strong inducement is provided for him to undertake work which, otherwise, he might not be able, or inclined, to begin. The greatest thanks of the Profession, therefore, are due to those who, like Dr. Waddell, have presented their mathematical work in tabular or graphic form suitable for general use. By doing so the mathematical part of the work has been reduced from a problem to a process, with the result that the engineer can devote more of his energies to that part of his work which may be described as "constructive art." Mr. Sales.

Problem No. 1.—On page 4 the author mentions "the lateral system in a simple truss bridge." There would seem to be some uncertainty as to what is exactly meant by this expression. Truss bridges are of two kinds, deck and through; and the latter is provided with a floor system in addition to the lateral system proper. Is it to be understood that the weight of the lateral system plus rail-girders plus cross-girders will offset that in the bracing of the floor system plus that of the rib flanges of the corresponding arch structure, plus that of the other diagonals between the arch ribs? Probably not; but the writer thinks that the fact might have been stated; or, what is still better, that the style of the structures in which the relative weights of parts are considered might be illustrated by clear diagrams. To bring Dr. Waddell's results into line with Indian conditions, much work will be necessary in connection with tabulating the weights of various types of spans designed for all gauges, and under different loadings.

The author refers to a very interesting point concerning a method for hinging the crown of two-hinged and three-hinged arches. His method is to hinge the crown at mid-depth for the dead-load stresses, and afterward to make both the upper and lower chords hingeless for the live-load stresses.

Problem No. 2.—The formula, $A = \dfrac{T + \dfrac{2M}{d}}{p_c}$, for the area of the

Mr. Sales.

chords, would seem to imply that the section will not be symmetrical about the neutral axis; and this, in fact, is what is found in the bottom raker struts and other principal members of certain cantilever spans where the top flanges are of greater area than the bottom ones. It would be interesting to know whether the contour of the arch rib can be placed so as to give symmetrical rib sections, and, if not, what rules are adopted to determine provisionally the position of the neutral axis.

The author frequently refers to the esthetic aspect of bridge design. His remarks lead one to regard esthetics as probably embodying economical principles hitherto unsuspected, except, perhaps, by experts. Whether mathematical considerations will eventually lead to true esthetics, or esthetics will indicate the true mathematical principles to be followed, are matters for speculation. It would be interesting to know what the author has to say on this subject. It would seem that the parabolic curve, so frequently adopted for the contours of arch ribs, is not a line of beauty, and that, under certain restricted conditions, arches might be reasonably made of circular form. The writer does not know whether this is generally possible, but thinks that the subject is worthy of investigation, as a slight increase in weight of metal might be compensated for by the better appearance of the bridge. Though there must be diversity of opinion on matters which are so often decided by individual taste and preference, yet the esthetics of bridges concerns every one, and, in such cases, guiding principles must be sought for, rather than an appeal made to what, after all, may be only traditional belief or sentiment.

Problem No. 3.—The placing of a hinge in a spandrel-braced arch is a problem which has been solved by the author in a very interesting manner. He points out that the conditions in light bridges are such that top chords are provided with sections which are in excess of theoretical requirements. By placing the hinge in the top chord, the superfluous metal is utilized, and the total weight in arch metal is considerably reduced. These are principles of construction which, to some extent, apply to simple-truss spans. It would be interesting to know how Dr. Waddell would design the ordinary through type of truss span so that the top lateral bracing could be arranged to assist the top chords to the utmost extent by taking a part of the compression to which these members are subjected. There seem to be strong grounds for believing that it actually does perform this office.

Problem No. 4.—The writer notes the author's conclusion that the spandrel-braced arch is lighter than the braced-rib structure for a 200-ft. span, but a little heavier for the 500-ft. span. The author, however, does not inform the reader whether the comparisons are made with hingeless, two-hinged, or three-hinged arches. Perhaps the relative weights are the same for all three types; but the point might have

been brought out in greater detail, and the part of the paper devoted to Problem No. 4 expanded considerably. Mr. Sales.

Problem No. 5.—The solution of Problem No. 5 is valuable. One of the first questions the bridge engineer will ask himself is: Is it justifiable to undertake an enormous amount of computation work to obtain stresses in a hingeless arch when perhaps, everything considered, the two-hinged or the three-hinged arch might, in the long run, be the most economical in metal and, from a practical point of view, be the best? The reader, doubtless, will be perplexed by the diversity of quoted opinions on the relative economics of the hingeless arch. One authority states that the hingeless is more economical than a two-hinged or a three-hinged arch; another that the three-hinged arch is the most economical; and still another that the hingeless type is more economical than the two-hinged and the three-hinged; and that the two-hinged is about as economical as the three-hinged. The whole question, however, turns largely on the rules used for allowances of metal for stresses of different kinds. Take the case, for example, of a truss continuous over two spans. Most engineers would consider that economy would be effected by making the span continuous; and yet the writer knows of a case where the spans considered singly were as strong as when considered as continuous. The ruling factor in this case was the extra allowance made under rules for the reversals of stress. Without that extra allowance the continuous girder would prove to be the most economical. Dr. Waddell finds that, if the extra effect of stress reversals is ignored, the hingeless and the two-hinged ribs will be lighter than the three-hinged ones; also, that, if the extra effect of stress reversals is allowed for, there is not much to choose as regards economy in favor of the two-hinged type over the three-hinged; also, that, if the extra percentage to be allowed for reversals is 75% instead of 50%, as some engineers specify, the weights of the two-hinged and three-hinged types will be alike. The author also considers temperature stresses, and finds that, if they are provided for without increasing the working stresses, there will be a 7% advantage for the three-hinged type; but if, on the other hand, a 20% increase of intensities of stress is allowed for the combination of the stresses due to all loadings and temperature effects, then the two-hinged type, as far as weight of metal is concerned, has the advantage over the three-hinged type. These conclusions are exhibited in Table 6, from which it is found that, both for railway and highway bridges, the hingeless arch is the heaviest, the three-hinged arch comes next, and the two-hinged is the lightest.

Problem No. 6.—The author, in a few words, describes the economics which result from a combination of the two-hinged and three-hinged types, by which the structure is three-hinged for the dead loads and two-hinged for the live loads. The relative weight of this combination,

Mr. Sales.

compared with the three-hinged structure, is estimated at 97% of the latter in the case of railway arches, and 99% in the case of highway arches. The advantages of the combination type over the three-hinged type are: greater rigidity in the moving load, and less difficulty and expense in erection.

Problem No. 7.—This part of the paper should be of great interest to Indian engineers, and the two layouts given by the author will be much appreciated should the occasion arise when an arch bridge is contemplated for a site where satisfactory anchorages cannot be found, but where it is desirable to secure the economy of such a bridge with its beauty of structure. The layout for a cantilever arch bridge indicates the lines on which designs of bridges might, with advantage, be prepared to span some of the well-known openings similar to those on Indian railways in hilly country. In such cases it is often found that the gorge abruptly descends to a great depth at a distance, say, of 100 to 150 ft. from the bank, and good rock foundations can only be found at some considerable distance below, and away from the abutments. The bridge shown by Fig. 14 seems to be an ideal type for these conditions. A layout for an arch bridge, with flanking simple-truss spans is shown on Fig. 15. It would seem that this design is not so adaptable for Indian conditions as Fig. 14.

Problem No. 8.—The author remarks that the bridge engineers of America were unable to furnish reliable data relating to the ratios of weights of metal in arch bridges and truss spans. He, however, evolves three formulas which give percentages to be applied to weights of metal in trusses of simple-truss spans in order to find the weights for arch ribs and the superimposed columns with their bracing to carry the same live loads. Results obtained from the three formulas are plotted for steam-railway, electric-railway, and highway structures as diagrams on Fig. 16. For spans of less than 100 ft. the economy of the arch bridge is not so marked, and ranges, roughly, from 75 to 100% of the simple-truss span. For spans of 300 ft., however, the percentage lies between 63 and 82. The diagram is instructive and comprehensive. It may be pointed out, however, that only the extreme limits of the percentages for 100-ft. and 1 000-ft. spans were computed, and the middle one interpolated by judgment. Diagrams of weights of metal in single-track, steam-railway arch bridges of carbon steel under seven classes of loading are given on Fig. 17, and similar information for double-track bridges on Fig. 18. Weights of metal in highway arch bridges of carbon steel with paved roadway on reinforced concrete base, and reinforced concrete sidewalks, and carrying a double-track electric railway at the middle of the deck are furnished for five widths of deck on Fig. 19. Weights of metal in single-track and double-track steam-railway arch bridges have been computed for nickel steel, and the results exhibited on the diagrams shown on Figs.

20 and 21. All these diagrams are valuable; and, although absolute accuracy cannot be depended on, for the reasons stated by the author, yet they are in most cases sufficiently so to enable the engineer to frame comparative estimates and fix the dead loads of an arch structure before preparing his final stress sheet. Mr. Sales.

DAVID A. MOLITOR,* M. AM. SOC. C. E. (by letter).—In this paper the author has presented, in very well arranged form, the conclusions deduced from an extensive set of calculations bearing on the economics of steel arch superstructures. As arch bridges have grown rapidly in popular favor, during recent years, in America, chiefly for esthetic reasons, such extensive investigations are both interesting and valuable. The findings, as recorded, though not always conclusive, will at least serve as a guide in designing, and will save others many unnecessary labors. Mr. Molitor.

"The Economics of Steel Arch Bridges," of course, would include economic relations between superstructure and substructure costs in any given case, and, though not intending any adverse criticism because this phase of the subject was neglected, and necessarily so, as only generalities could be treated and the substructure always depends on special conditions, yet the paper does not cover all that is implied in its title.

The comparison between arch and simple truss superstructure weights is of limited value, because the cost ratio is generally reversed when the substructures are considered.

The fundamental problem in the economics of arch bridges consists in solving the conditions for economic span lengths for a given bridge profile comprising many spans. It might be supposed that any set of spans complying with the economic rise to span-length ratio would fulfill the requirements for a complete structure. In other words, any intermediate span would have a length of about four times its available rise. This would be true only for exceptionally favorable foundation conditions, for which the cost of piers and foundations might become relatively negligible. However, span lengths thus chosen would never result in maximum economy for end spans and for less favorable foundation conditions. Thus, the author's answer to his first problem is not conclusive, as he deals only with proportions of superstructure dimensions. His economic rise to span-length ratio, therefore, is correct only for a single span of the superstructure, as for a bridge spanning a rocky chasm where no expensive abutments are required.

Generally, however, the author's ratio must be increased until the resulting horizontal thrust is reduced to an amount where the cost of abutments attains a consistent minimum. This frequently leads to a ratio approaching 0.5, resulting in a small increase in cost of super-

* Detroit, Mich.

Mr. Molitor.

structure, which will be more than equalized by the saving thus accruing to the abutments, if it is a single span, or to the piers for an intermediate span.

Although such a high ratio is practicable, especially for stone and concrete arches, yet the shape of arch resulting therefrom is not always pleasing from the esthetic viewpoint, which so frequently interferes with economic considerations.

Hence, for all practical purposes, one might adopt the rule, that the rise-span ratio should be chosen so that it would produce the best general appearance for the least total cost of structure. This rule, probably for centuries, has received tacit acceptance without getting into print.

The author states that "in order to cover effectively the ordinary range of span lengths for arch designing, it was necessary to compute for three lengths." The writer wishes to point out that it requires more than three points to fix a curve or law, and even four points might prove inadequate for empiric laws of the kind here sought.

In solving Problem No. 2, the author's reasoning in finding the economic rib depth for braced-rib arches is not clear. He first explains that this question does not arise in the case of solid-rib arches, because the rib acts both as a beam and a strut, and then proceeds to apply the economic criterion of ordinary girders (whether solid or open-web) to the braced rib, which likewise resists bending and compression. The only difference is that open-web bracing carries shear only, while the chords or flanges receive direct stress from arch thrust. Hence, in neither case does there appear to be any justification for the assumption that the economic depth, d', is one for which the chord area, A_m, is equal to the web area, A_w (for live load only), even when the rib center line is properly located.

The suggestion of making the arch depth, at mid-span, equal to from 6 to 8% of the span length, for spandrel-braced arches (presumably three-hinged) seems to be contrary to economy; and the uniformity in chord sections, resulting from rib-depths proportional to the bending moments, is, in the writer's opinion, a decided economic advantage, both in weight and in design, which should not be disregarded.

It is strange that the author did not give more attention to the question of the economic shape of the arch center line, as even slight deviations affect the weight of superstructure very detrimentally, and any resulting increase in weight affects the cost of abutments and foundations. This, perhaps, is the most important general principle in arch economics, which has been shamefully disregarded in the past, though it more vitally affects concrete and masonry designs. Actually, the eight economic problems treated are more or less secondary in importance to the economic shape of the arch center line.

Mr. Molitor.

In his paper, "Three-Hinged Masonry Arches; Long Spans Especially Considered",* the writer showed that the center line of the arch ring should be the resultant polygon drawn for the full dead load plus one-half the uniformly distributed live load (including impact), acting over the entire span, to produce the maximum economy in material for the unsymmetric maximum and minimum live-load conditions.

The writer again discussed this economic feature in his treatise, "Kinetic Theory of Engineering Structures," on pages 305 and 323, and shows, further, on page 307, that an arch ring, formed to meet this condition, can never be truly circular or parabolic in shape. The resultant polygon becomes a circle when the superimposed load at the springing points, for semicircular rings, becomes infinite. This polygon becomes a parabola for an absolutely uniform load per foot of bridge. Neither case of loading can be realized in practice, though very flat arches closely approach the parabolic shape.

A very important result, obtained from a proper choice in the shape of the arch ring, is that all normal sections of the ring will be symmetric with respect to the axial line, or resultant polygon. A further economy in detailing will thus be accomplished, because the equal maximum bending moments (positive and negative) for each section will also have attained their smallest values for any given depth of ring.

Although this matter is most important when dealing with concrete and masonry arches, it remains a significant factor in the design of large metal arches, but may be neglected, for esthetic reasons, on small bridges.

The author is inclined to adopt the same economic rib depth for three-hinged, two-hinged, and hingeless arches, and then says that for large two-hinged arches, such as the Hell Gate Bridge, the depth should vary in proportion to the bending moment. He finally states that esthetics and rigidity should never be sacrificed for the sake of economy in weight of metal.

These several statements regarding the economic depth of arch rib, which are quite inconclusive and at variance with each other, might have been condensed into the simple rule—do as you please, or as you think best.

In considering Problem No. 3, which deals with the location of the crown-hinge of a three-hinged, spandrel-braced arch, in either the top or bottom chord, it would appear to be almost self-evident that less material would be required for the top chord hinge because the horizontal thrust is diminished by the greater rise resulting from this layout. The same circumstance would have an economic effect on the substructure or abutments. Hence, it is prudent to choose a minimum crown depth consistent with good details.

The conclusions found for Problem No. 4 are apparently correct,

* *Transactions*, Am. Soc. C. E., Vol. XL (1898), p. 61.

Mr. Molitor.

provided the bottom chord of the spandrel-braced arch is formed to meet the economic requirement for shape. The solid-rib arch is necessarily somewhat wasteful of metal, especially in the web, precisely as for simple plate girders. The braced rib having two compression chords of about equal sections will usually require more metal than the single bottom chord of the spandrel-braced arch, where the chord section is consolidated and the bending moments are carried by the spandrel bracing in direct stress.

Regarding Problem No. 5, the author's conclusions, on the relative economics of hingeless, two-hinged, and three-hinged types, are, after all, based on a somewhat meager assortment of data, despite his labors expended toward its solution. In the first place, he did not give due consideration to the special advantages accruing to each type (as a time-saving expedient), and hence the weights found are not strictly comparable. The assumption of a single value of impact for all truss members is in itself sufficient to wipe out the comparatively small weight differences sought, as the loaded lengths governing the critical stresses in a member, similarly located in each type, is materially different, which may be shown by a comparison of the influence lines for the three cases.

Under such circumstances, it is not at all surprising that he found the economics of the three types depending almost entirely on the "method of treating reversing stresses, and the importance accorded to temperature stresses." This raises the pertinent question regarding the applicability of specifications to arch bridges, when such specifications were developed for simple truss bridges only. There are numerous inherent differences between arches and trusses not covered by the ordinary bridge specifications, and any one familiar with arch designing will realize that these differences will suffice to explain the disparity between the author's conclusions and the findings of others quoted in the paper.

The writer can see no justification for treating reversing stresses according to the author's specifications for truss bridges, as the two cases of stress are produced at different times, by widely different loadings (both in position and magnitude), and different impact, and, therefore, can have no simultaneous static effect on which to base the section of any one member. Furthermore, the formulas of Launhardt and Weyrauch, based on the experiments of Woehler and Bauschinger, furnish no justification for applying the principle of fatigue to the design of any bridge members, as is best shown by referring to the experiments themselves. On this point see "Fatigue of the Material."*

Hence, all that can reasonably be required is to design each member so that it will withstand safely its maximum and minimum conditions

* "Kinetic Theory of Engineering Structures", p. 265.

Mr. Molitor.

of stress, one at a time, without exceeding the allowable units of stress for each condition. Ordinary prudence would require some provision for a future increase in live load and still have a structure of uniform strength throughout, relatively to the elastic limit of the material. This can be accomplished by designing all web members, or those in which the total stress is not proportional to the total loading, for such augmented live loads on the basis of appropriately higher unit stresses, chosen so that the actual unit stresses shall exceed the allowable values in a constant ratio.

To make this clear, suppose the structure is to be made safe for 100% overload in live load only (which is extreme), then the D. L. + 2 (L. L. + *I*) stress in the chords may become, say, 1.6 times as great as for D. L. + L. L. + *I*, depending on the relative magnitude of D. L. to L. L. This would result in raising the allowable unit stress 1.6 times, or to, say, 80% of the elastic limit. Then, if the web system is designed for stresses resulting from this same overload, using unit stresses 1.6 times the allowable values, the structure will be of uniform strength throughout with respect to the elastic limit of the material, for live loads equal to twice those normally assumed. This is the writer's method of designing all structures, and puts the extra material where required to strengthen the weakest parts.

From theoretic considerations alone, the relative weights of metal, for the three types of arches, should be approximately as given by Malverd A. Howe, M. Am. Soc. C. E., quoted on page 19. However, local conditions and practical reasons frequently preclude the possibility of adopting the most economic type (the hingeless), especially for long-span bridges. Also, as pointed out before, the weight of superstructure alone, does not usually decide the economic status, so that each case will still require investigation for the conditions peculiar to the site. The rise-span ratio, also, has an important bearing on this problem, and may be a determining factor, especially for large half-through arches like the Hell Gate Bridge.

The conclusion to Problem No. 6 leaves no room for comment, as the larger variables are here eliminated and the answer becomes more or less obvious.

The cantilever arch bridge, which received attention in Problem No. 7, represents a type which has not been fully appreciated, though its application is somewhat limited; but, where the profile and foundation conditions fit such a layout, there is certainly every argument in favor of a two-hinged cantilever arch. The stress calculations offer no special difficulties, provided influence lines are used. Any other method of calculation might prove hazardous on account of the complicated load positions for critical stresses. The author's findings relative to the proportions of span lengths are very valuable.

Mr. Molitor.

It should be mentioned that a three-hinged cantilever combination is usually undesirable, and may possibly result in unstable forms.

The final weight curves, presented under Problem No. 8, for arch superstructures, constitute a valuable contribution to our meager knowledge of this subject. These curves will at least save the labor of a preliminary weight calculation in most cases, thus permitting the designer to proceed at once to a fairly comprehensive stress analysis.

Exception might be taken to the author's reasoning applied in finding the maximum possible span length for three-hinged arches. He makes W_a infinite and finds the corresponding span length, $l = 3\,540$ ft.; but W_a is the weight of metal per linear foot of span, and when this is infinite, the dead-load stresses in all principal members become infinite. This is evidently not an answer to the question of what span length will result in such a dead load that the unit dead-load stresses in the members will not exceed the maximum allowable values normally assigned for total dead plus live load. Even this span length, if known, would exceed all limits of usefulness, as a bridge of this span could carry no live load.

The other assumption: "that the said limit is reached when it takes $4\frac{1}{2}$ lb. of metal to carry 1 lb. of live load," leads to a very much shorter span, which the author estimates at about 2 000 ft., though this would lead to an enormously expensive bridge.

The author's opinion "that if more were known generally concerning the weights of metal in steel-arch structures, their economic functions, and their comparative economy in respect to the corresponding simple-truss structures, the esthetic type would be adopted more frequently, in spite of the greater labor it involves in both designing and construction," does not appear as a real excuse for not adopting the arch type whenever that type is warranted.

In the first place, the weight data referred to are merely a convenience and, if unknown, do not constitute a deterrent factor to any one of earnest endeavor, as is manifested by the numerous steel arches designed in the past. Then, also, the greater labor involved in designing arches depends very much on an appropriate choice of the methods used, and on the competency and experience of the designer; but the greatest obstacle to popularizing arches is, perhaps, the personal bias frequently expressed against this type by bridge engineers themselves, owing largely to a limited familiarity with this more specialized branch of bridge engineering.

In fact, the author himself has frequently expressed his views adversely to all structures involving redundancy, and his present effort may be accepted to indicate that he is gradually changing his views on this subject.

It is the writer's opinion that arches of steel, concrete, or reinforced concrete, should receive the first consideration, whenever the profile,

site, and foundation conditions warrant their construction, regardless of any lack of preliminary weight data, or the slightly greater labor involved in their design. In thus minimizing the difficulties and expenses attending such designs, he is actuated by the results of his own experience, with the general comprehensive methods (mostly graphic), presented and advocated in his recent treatise previously referred to, and which can be more fully appreciated by any one who will approach the subject with an open mind. That many bridge engineers have neglected to post themselves, is manifested by articles in current literature and professional papers, where cumbersome and obsolete methods are often presented as new and novel. Mr. Molitor.

The author deserves much credit for his present contribution on arch economics, a subject about which little has been published. The paper points the way to accomplishing more in this direction, and emphasizes the importance which the designer should give to economic studies.

EDWARD W. STONEY,* ESQ. (by letter).—The writer has read with great interest this most valuable paper, but regrets that he is unable to add usefully to its discussion, as Indian engineers have had no occasion to consider, or opportunities to use, metal arch bridges. Mr. Stoney.

The many large and long railway bridges which have been built in India are generally over sand and silt river beds of great depth, and require foundations sunk to from 100 to 150 ft. below these beds; in fact, at the "Lower Ganges" Hardinge Bridge, recently built under the supervision of Sir Robert R. Gales, the foundations are from 180 to 185 ft. below the river bed.

The banks of these rivers, also, are often but little above the river beds, so that arches would be quite unsuitable because as much waterway as possible has to be provided, without unnecessarily raising the approaches.

The writer thinks that the economics and costs of maintaining girder and arch metal bridges of similar span might be given by American engineers who have had to do with both. The maintenance of long-span girder bridges with intricate systems of bracing causes considerable expense, trouble, and anxiety to railway men.

The writer desires to invite the attention of American engineers to a rather remarkable book† by the late Sir B. Baker, Hon. M. Am. Soc. C. E., entitled "Beams, Columns, and Arches", in which the author discusses metal arches, gives simple formulas for computing their approximate dimensions, and compares the results obtained thereby with the elaborate calculations made by the late Capt. J. B. Eads, M. Am. Soc. C. E., for the St. Louis steel arch bridge.

* Coonoor, Madras Presidency, India.

† Published by E. F. Spon, London, 1870.

Mr. Stoney. The writer would also call attention to the paper* entitled "Curve of Equilibrium for a Rigid Arch under Vertical Forces", by Mr. George Fuller. In this paper Mr. Fuller shows how this curve may be derived graphically, at once, from the bending moment diagram produced by these forces.

Mr. Frankland. F. H. FRANKLAND,† M. AM. SOC. C. E. (by letter).—Owing to the wide divergence of opinion regarding certain economic functions of arch design, which is shown by the writings of Howe, Merriman and Jacoby, and others, and well illustrated by the tabulation of the principal steel arches of the world given in the discussion by Charles E. Fowler, M. Am. Soc. C. E., the writer considers the author's investigations concerning the economics of steel arches of very great value to the Profession, especially as they constitute the first systematic attempt at the solution, so far as he is aware, of the primary problems pertaining to arch design. Mr. Fowler's discussion undoubtedly adds materially to the value of the paper, and he is to be commended for the energy and hard work shown in compiling the table of bridges. It is to be noted that Mr. Fowler has omitted from his table any mention of the three arches calculated by the late C. R. Grimm, M. Am. Soc. C. E., and illustrated in his paper "The Arch Principle in Engineering and Esthetic Aspects, and its Application to Long Spans".‡

Mr. Grimm stated that his comparison of five designs for one crossing, where the central opening was the same, *viz.* 1 800 ft., showed the total metal in the superstructures to be as follows:

1.—Cantilever bridge.....	70 000 tons
2.—Suspension bridge.....	60 000 "
3.—Arch bridge (1 800-ft. central span flanked by two crescent arches)..	53 000 "
4.—Arch bridge (1 800-ft. central span flanked by two tied arches).....	45 000 "
5.—Arch bridge (1 000-ft. arch span at center, flanked by two cantilever truss spans, each projecting 400 ft. beyond main piers).....	45 000 "

Mr. Grimm's computations and speculations are especially interesting, from the point of view of economics. His computations, however, applied to the superstructure only, and it must be borne in mind that a consideration of the substructure design might have caused the total costs of his five cases to assume a different order in economy.

The author's well-known characteristic of "stick-to-it-ive-ness" is illustrated by the subject of his paper. In 1897 he wrote § as follows:

* *Minutes of Proceedings*, Inst. C. E., Vol. XL (1874–75), p. 143.

† New York City.

‡ *Transactions*, Am. Soc. C. E., Vol. LXXI, p. 233.

§ "De Pontibus."

Mr. Frankland.

"In concluding this chapter, the author desires to call attention to the fact that there is still a great deal to be learned about the designing of arches; and to suggest that some professor of civil engineering, who is well posted on bridge designing and who has time to spare, could spend several months to the great advantage of the engineering profession in determining the proper relations of span length, rise, arch depth, width between exterior arches, etc., for the various styles of arch, and in ascertaining the relative economics of the latter."

and, in 1915, he stated:*

"For many years the author has been endeavoring to establish some approximate relation between the weights of metal per lineal foot for trusses and laterals of arch bridges and those for the corresponding simple truss bridges; but has met with very little success. He once submitted the question to his brother bridge specialists of America, but they were unable to throw any light upon the subject, because their opportunities to design and build arch bridges had been few and far between, and because the ratio of rise to depth has a great effect upon the weight of metal in an arch. Of course, there is for any span length some economic value of that ratio; but it is not yet known, and it probably varies more or less not only with the span but also with the type of construction. The only practicable method of determining the original question would be to settle first that of the economic ratios of rise to span, design a few arch bridges with the said ratios, and make the comparison. This would have to be done for the solid-rib, the braced-rib, and the spandrel-braced types to make the job complete, adopting for the first set of curves the three-hinged type, and afterward modifying the results for the other three types of hinging. It is evident that the amount of work involved in such an investigation would be immense. It should be done by an experienced bridge designer, as the results would be worthless if obtained by any other investigator. The author suggests that one of his younger brother-specialists undertake the investigation."

Between the writing of "De Pontibus" and "Bridge Engineering", the author made several systematic attempts to induce other engineers to undertake such an investigation, but without success. He even went so far as to attempt to induce some technical institution to agree to give doctors' degrees to two bridge specialists who would do the work jointly, but that failed to materialize.

Generally speaking, practical as well as economic considerations point to the use of two-hinged, spandrel-braced arches as probably the best type to use for railway traffic, provided that the natural abutments permit of sufficient rise, which is often the case where the selection of an arch design is a logical solution of a particular problem. The spandrel-braced type of arch is less subject to vibration and is more rigid than any other type; and it is peculiarly suited to easy erection by the cantilever method, as was done in the case of the author's 425-ft. span

* "Bridge Engineering."

Mr. Frankland.

arch bridge on the Canadian Northern Pacific Railway over the Fraser River at Lytton, B. C. The inclination of the arches to the vertical contributes greatly to rigidity, this being particularly noticeable in the Fraser River structure.

In connection with the erection of two-hinged arch bridges it is customary nowadays to adopt an expedient to obviate the usual necessity of introducing the calculated stresses due to dead load and temperature in the top chords at the center by the use of powerful jacks, or other means, before the final point can be riveted up. The expedient referred to consists in assuming that the dead load and temperature stresses in the top chord at a certain selected temperature are zero, the arch acting as a three-hinged structure under these conditions, namely, with all dead load in place and at the selected temperature. The span, therefore, is erected as a three-hinged structure, all dead load, or its equivalent, including the decking, being placed thereon, and at a time when the actual temperature is as close as possible to that previously selected. The center panel of the top chord is then easily inserted and riveted up. This expedient was used by Ralph Modjeski, M. Am. Soc. C. E., for the erection of the two-hinged, spandrel-braced, arch bridge for the Oregon Trunk Railway in the Crooked River Canyon, and by Gustav Lindenthal, M. Am. Soc. C. E., for the erection of the Hell Gate Arch.

It might not be out of place to mention here the frequent error which some make in considering arches of the Hell Gate and Detroit-Superior type as being of the so-called "open-web" type. Although the two instances cited have curved top chords, principally for the sake of appearance, they are both essentially "spandrel-braced" arches, which usually have straight horizontal top chords. Both the Hell Gate and Detroit-Superior bridges have special provision in their design to guarantee that the wind stresses would be taken to the lower chords and would not be transmitted to the top chord. The reason for this is obvious, and is symptomatic of the spandrel-braced as compared with the open-web type, where the main stresses are usually divided between top and bottom chords and are transmitted equally thereby to the skewback hinges.

It appears to the writer somewhat surprising that the cantilever type of steel arch has not been used more frequently in America, although its applicability to certain conditions has long been recognized in Europe. As the balancing of the moments about the hinges very materially reduces the horizontal reactions at the abutments, it is possible in many instances to effect a material economy by the utilization of this type. The two best-known examples of the cantilever arch are the Viaur Viaduct, in France, and the Rio Grande Bridge, on the Pacific Railway, in Costa Rica. This type of construction is particularly easy and economical of erection by the cantilever method.

Mr. Frankland.

The economic gain of the arch over the truss bridge is greater in highway than in railway bridges, for several reasons, chief among which is the smaller ratio of impact allowance to total dead load. This is the principal reason why three-hinged arches are more suited to highway than to railway structures.

It would seem that the use of nickel steel in arches, where the ratio of rise to span is small, would materially affect the economics, since the reduction of horizontal thrusts at the abutments, due to reduced dead load, would be considerable. This, however, is a question of balancing the increased pound price of the alloy steel against the saving in weight of steel, plus the increased economy of the abutments.

The writer feels impelled to mention one consideration governing the economics of arch bridge design which the author has not noted in his paper, perhaps because it relates to substructure design. The important bearing on economics, in this connection, is, as to whether or not it is possible to place all the piers of an arch bridge on the same kind of foundations, rock or pile. It is well known, of course, how extremely unwise it is to found one abutment on rock and the other on piles. The consideration of this condition has quite recently been experienced by the writer in his practice, the instance being of a certain concrete arch bridge, with a bascule span at approximately the mid-point, thereby dividing the structure into what are really two arch bridges. The rock outcrops near one end but dips toward the other end, so that the depth to rock makes it impracticable to found the entire structure on rock. It will be necessary in this case to carry the piers to rock for one-half of the structure and to carry the piers of the other half on piles, although by doing this the deepest abutment on rock and the shallowest abutment on piles are, considered alone, uneconomic.

The writer ventures to express the opinion that there have been numerous occasions when an arch design would have been more economical than the truss design which has been adopted. Perhaps this has sometimes been caused by the "bogey" of the computations involved in the arch design. He thinks that this bogey would be readily dispelled if bridge engineers were to make more common use of the graphic instead of the analytic method of finding the stresses. The graphic method is not only shorter, but is self-checking, and it enables the computer to follow each step very clearly. If any should doubt this assertion, let him try both methods on the same problem and become convinced. Means of popularizing the building of arches in many places similar to those where truss and cantilever spans have been adopted, such as papers like the author's, should be strongly commended.

Steel arch bridges are generally suitable only for those sites where natural abutments exist, or where the surroundings are such as to call for special attention to esthetics. The latter is probably one of the

Mr. Frankland.

principal reasons why a larger percentage of bridges in Europe are of the arch type, although it is undoubtedly true that, as a rule, bridge sites in Europe offer greater natural advantages for arch design than have so far existed in the Western Hemisphere. However, with the continued development of North and South America, rougher terrain will be brought under the hand of civilization, and this difference will, to a great extent, eventually disappear. Consequently, it seems to the writer that an increasingly large number of arch bridges will be built in the United States.

The application of economic theories of arch design is necessarily restricted by the local conditions at the site, which invariably govern the ratio of rise to span, and the proper determination of the true economics calls for more judgment on the part of the designing engineer than with any other type of bridge. By "judgment" the writer means the developed engineering judgment which comes from long practical experience in problems relating to the choice of location and the right interpretation of existing conditions.

Some bridge engineers seem to be imbued with the idea that, if natural rock abutments do not exist, it is not worth while to consider the feasibility of an arch for a particular site. In refutation of this erroneous idea, the writer begs to draw attention to the concrete arch structure having the longest span in the world, the hingeless arch of 327-ft. span over the Tiber at Rome. As is well known, the abutments for this bridge are founded on alluvial silt. In this case, other conditions than those of economics were predominant.

Particularly noticeable in the paper is the neatness of the method used in determining the economic ratios given in Fig. 13 by means of Fig. 12, as is also the usefulness of the equations given on page 27.

Mr. Waddell.

J. A. L. WADDELL,* M. AM. SOC. C. E. (by letter).—The hearty thanks of the writer are tendered to all who have done him the honor of discussing his paper, and especially to Mr. Fowler for the many weeks of hard work which he devoted to the compilation of the table of data (Table 8, Plate I) concerning one hundred long-span arch bridges. It is a matter of regret that there were not more contributors to the discussion, especially as so many were asked individually to take part therein. The reason for this, undoubtedly, is the very limited amount of knowledge in the Profession, previous to the publication of the paper, concerning the economic questions treated and the weights of metal in steel arch structures.

Of the eight primary economic problems set originally for solution in this paper, six were solved by making special designs and subsequent computations of weights of steel, thus settling, for these cases, beyond

* New York City.

Mr. Waddell.

all doubt whatsoever, the question of economy of metal; but the other two were based on certain semi-rational, semi-empirical formulas that give the approximate weights of carbon steel in braced-arch ribs. In these problems the validity of the conclusions reached in the investigation was legitimately subject to question; and that question was raised by Mr. Fowler, who based his criticism mainly on averages of percentage functions taken from the very complete table of long-span arch bridges which he compiled.

He showed that the writer's economic ratios of rise to span length for the different types of arches agree fairly well with the superior limits found. Possibly this is merely a fortunate coincidence, because designers are often prevented by ruling conditions from adopting what they might deem to be economic ratios of rise to span length; but, on the other hand, it might be considered by some as corroborative evidence of correctness.

In the other of the two problems, however, *viz.*, the economic depth of arch ribs, there is seldom any condition precedent which should prevent a designer from adopting approximately the most economic depth; and hence averages of depths of ribs of existing arches should show what the general impression of designers has been concerning this question of economics. Mr. Fowler computed these averages and found results considerably lower than those which the writer determined by the use of his before-mentioned formulas for weights of arch ribs. From individual judgment, based on these averages, and on the writer's findings as well, Mr. Fowler determined certain compromise economic depths varying from 2.5% for plate-girder arches to 4.0% (and in one case 4.3%) for lattice-ribbed arches. Instead of 4.0%, the writer had found 7.5% as the most economic depth, but had pointed out that a material variation can be made therefrom without greatly increasing the weight of metal in the arch, also that "any variation that is likely to be adopted will be a reduction; because, generally, the appearance of the arch is improved by making its rib depth smaller than the economic one." Computations made from Fig. 6 show that, on the basis of the writer's original investigation, decreasing the ratios of depth of arch rib to span length would give certain percentage increases in weights of metal in the ribs. These are shown in Table 12.

In view of the preceding, it is evident that the writer, when proportioning an arch rib, would probably have adopted, for esthetic reasons, a depth equal to about 6% of the span length, notwithstanding the fact that he had shown the theoretically economic depth to be 7½% thereof.

When Mr. Fowler challenged the findings of the investigation on this point, the writer stated that he would prepare four designs and estimates of weight for the ribs of a 500-ft. span, double-track railway, three-hinged arch bridge, so as to plot a curve indicating the actual

Mr. Waddell.

economic depth; and he has since done so, the depths chosen for trial being 3, 5, 7, and 9% of the span length. These layouts are shown to scale on Fig. 32. The computations of stresses were made by the writer's Assistant Engineer, Mr. Francis De Schauensee, using the modern method of influence lines, but, in accordance with the writer's suggestion, checking one set of figures by the old established system of unit panel loadings. Although the check, of course, was not exact, it was sufficiently accurate for all practical purposes.

TABLE 12.

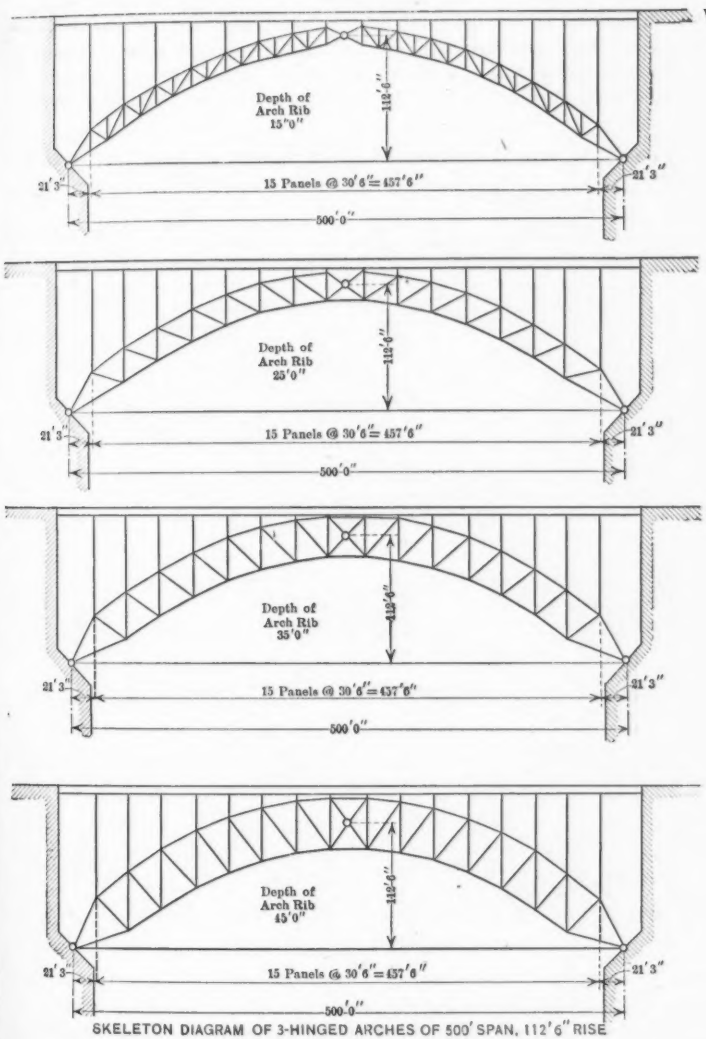
Ratio of depth of arch rib to span length.	Percentage increase in weight of metal above minimum in arch rib.	Ratio of depth of arch rib to span length.	Percentage increase in weight of metal above minimum in arch rib.
0.75	0.00	0.55	2.75
0.70	0.20	0.50	4.20
0.65	0.65	0.45	6.80
0.60	1.30	0.40	10.50

With these stress sheets as a basis, and using the designing specifications of "Bridge Engineering", the writer computed the sectional areas of all the main rib members and measured their lengths from the diagrams, reducing properly those of the web members to allow for their failure to reach the center lines of the chords. Then he multiplied each tabulated sectional area by the length of the piece, added the results, and multiplied the sum by 3.4, the product representing the weights of the main members, exclusive of the details. All the latter, in which the weights thereof are approximately alike for the four cases, such as stay-plates, connecting plates, diaphragms, hinges, and rivet heads, were omitted, but the weights of the splices and the lacing angles were computed and added in. The four quantities thus found were used as "comparing weights" to settle the economic question which was being investigated.

These "comparing weights" were plotted on Fig. 33, and a curve was drawn through the located points. Considerable thought was given to the drafting of this curve between the limits of 5% and 3% depths, owing to the abnormality of the latter layout. It would have been somewhat more accurate to have computed the weight for a 4% depth, but the time and expense involved thereby did not appear to be justified. From this curve, it will be seen that the economic depth of the rib for this span and for railway loading is 6½% of the span length, instead of 7½% thereof, as previously determined.

Recognizing that the making of a corresponding set of calculations for a highway bridge would be a comparatively simple matter, all

Mr. Waddell.



SKELETON DIAGRAM OF 3-HINGED ARCHES OF 500' SPAN, 112'6" RISE

FIG. 32.

Mr. Waddell.

stresses being found by slide-rule, the writer concluded to investigate the correctness of his previous finding, *viz.*, that the economic rib depths are the same for both railway and highway bridges. Some *à priori* reasoning, based on the manner of variation of the governing adjusted total stresses, had led him to the conclusion that these eco-

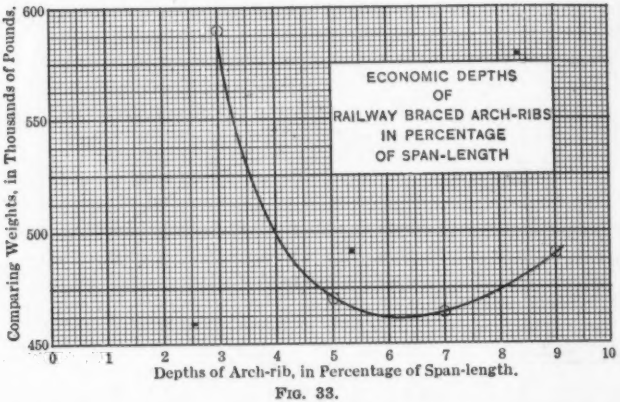


FIG. 33.

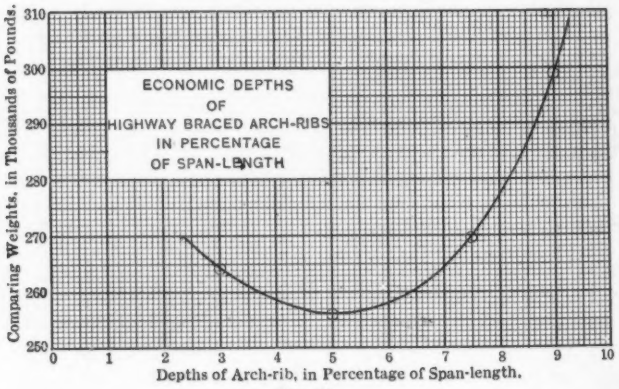

FIG. 34.

nomic depths would be less for highway arches than for railway arches, the factor of main influence being stress reversion in chords, which influence, of course, augments as the ratio of live load plus impact to total load increases.

Mr. Waddell.

Estimates of "comparing weights" were made as before for depths of 3, 5, 7, and 9% of the span length, and the results were plotted on Fig. 34, from which it will be seen that the economic depth for this case is 5% of the span length.

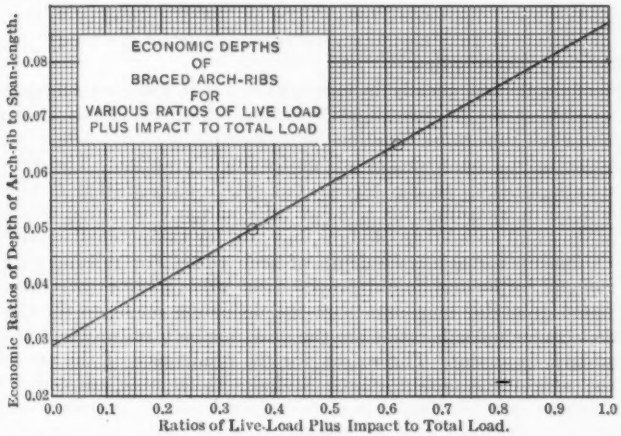

FIG. 35.

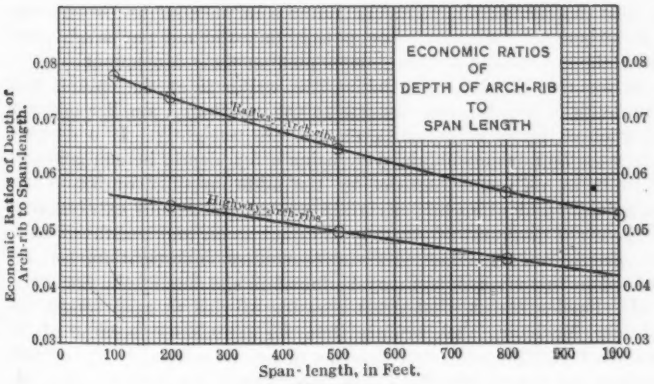

FIG. 36.

These two sets of figures permitted the determination of the manner of variation of the economic depth with the ratio of live load plus impact to total load, as shown on Fig. 35. The two points enclosed in circles on that diagram indicate the economic-depth ratios correspond-

Mr. Waddell.

ing to the ratios of live load plus impact to total load, in the case of railway and highway arch spans of 500 ft. By joining these points with a right line and extending this line in both directions, we obtain the data from which, by using Figs. 18 and 19, the diagram in Fig. 36 has been prepared. That diagram shows that the economic depth ratio for railway arch ribs varies from 0.078 for 100-ft. spans to 0.053 for 1 000-ft. spans; and for highway arch ribs from 0.056 for 100-ft. spans to 0.042 for 1 000-ft. spans.

These depths are greatly in excess of the 0.04 ratio established by Mr. Fowler; and the investigation proves that, in endeavoring to ascertain such important functions as economics, it is not safe to base one's conclusions on averages of professional practice. The writer feels greatly indebted to Mr. Fowler, not only for the good work which he has done in compiling his table of information concerning existing arch bridges and arch-bridge designs, but also for having challenged the writer's finding for economic depth of arch ribs. For railway arches the economic ratio first found proves to be all right for short spans, though too great for long ones; but the deduction made, to the effect that the economic-depth ratios are the same for both railway and highway bridges, is wrong. The reason for the occurrence of the error is that the weight formulas for arch bridges, which were adopted as a basis for the investigation, were of a too empirical character to warrant their use for the economic-rib-depth study, although sufficiently accurate for that of the economic ratio of rise to span length. The probable explanation of engineers' failures in the past to use economic depths when designing arch ribs is that they did not pay much attention to the question of economy when making their determinations.

As for the question of esthetics, the writer is of the opinion that a rib depth of 6% is more pleasing to the eye than a smaller one, and that such extremes as 3% or even 4% are unsightly. If a designer prefers the appearance obtained by using a 5% depth, he can generally obtain it in railway structures by the addition of 2 or 3% to the minimum weight of metal—certainly not a very serious extravagance.

The eight diagrams of stresses, sectional areas, and lengths of members, prepared in making this supplementary investigation, are not included in this résumé, but may be found in the files of the Society.

Mr. Fowler claims that greater ratios of rise to span length are necessary for heavy arch bridges than for light ones, because of the element of rigidity, and, therefore, he questions somewhat the writer's findings; but, concerning this claim, two facts should be borne in mind:

First.—The writer's investigations were made for economic depths, and, therefore, not necessarily for the best depths to adopt for all cases and all conditions; and

Second.—The economic ratios of rise to span length found by the writer are never small, varying as they do from 0.20 to 0.28 for solid-

Mr. Waddell.

rib structures, being 0.25 for spandrel-braced structures, and lying between 0.225 and 0.38 for braced-rib structures. Mr. Fowler's table shows, for structures of these three classes, respectively, the following averages: 0.18, 0.197, and 0.202, as against 0.24, 0.25, and 0.3 by the writer. Mr. Fowler's corresponding recommended averages are, respectively, 0.22, 0.254, and 0.272.

From this it is seen, that by taking averages for these three groups of averages, *viz.*, 0.193, 0.263, and 0.249, the writer's economic ratios of rise to span length, on the average, are 36% greater than those hitherto adopted by the Profession and 6% greater than those recommended by Mr. Fowler.

The reason that, in truss bridges, light structures, for economy of metal, require smaller truss depths than heavy ones is because of the greater values of $\frac{l}{r}$ in the web members; but, in arch bridges, this condition is cared for by varying the ratio of depth of arch ring to span length, and not by changing the ratio of rise to span length.

Mr. Thomson's suggestion that, in very heavy steel bridges, box sections for chords be used, is an excellent one, and the writer for years has been advocating this innovation. In making the plans for the Fratt Bridge, over the Missouri River, at Kansas City, he adopted the closed section; but the innovation was too drastic for the manufacturer, who was also the erector of the structure, and the plans were modified to agree with current practice, in order to comply with his wishes.

Mr. Farr asks why the writer, in Tables 4 and 6, gives the weight of metal per linear foot "per side" for ribs and lateral system, while in Table 5, he gives it in pounds per linear foot of structure. The answer is that, throughout the paper, comparisons were made by excluding all weights common to the structures compared, and hence the floor-system weights were generally omitted, and one side of the structure only was considered. In Table 5, however, it was desired to show the variations in the total weights of metal per linear foot in the three types of construction, consequently, that of the floor system was included in the totals.

When Mr. Farr says: "The economy in the weight of metal in the arch over the simple truss appears, from the information in the paper, to commence at spans of more than 1 000 ft., etc.", and "As it is only in the larger spans of more than 1 000 ft. that any economy in weight is shown over even a simple truss, and as the span at which the arch will come out lighter in weight than the continuous truss will be very much more than 1 000 ft., etc.," it is evident that he made a mistake in reading Fig. 16; for, in railroad bridges, the economy of the arch is shown to begin at spans of about 100 ft. and not at 1 000 ft., as he claims, and, in highway structures, the arch bridge is indicated as always being more economic of metal than the truss bridge. There is

Mr. Waddell.

no good reason for this misinterpretation, because the title of Fig. 16 reads "Percentages to Apply to Weights of Metal in Trusses of Simple-Truss Spans in Order to Find the Weights for Arch Ribs and the Superimposed Columns with Their Bracing to Carry the Same Live Loads"; and there is no percentage recorded that is as great as 100.

Answering Mr. Van Cleve's remark that "To place a field splice across the crown-hinge would undoubtedly be possible, but, in the speaker's opinion, would rarely be justifiable, owing to the quantity of splice metal required, and the expense of the field drilling", the writer would reply that this expedient has already been adopted, and without much trouble or expense. If the filling-in is done at an average temperature, the field work involved is very simple, but, at any other temperature, some special apparatus is required. The good results gained by the insertion of the additional members are worth many times the extra expense involved.

Answering Mr. Sales' remark that "Nevertheless, it is to be hoped that, judging by past experience, the author will find time to write a treatise on arch bridges, and include in it all the diagrams and preliminary work for which space could not be found in his paper", the writer would state that, some time ago, he arranged to do almost that very thing by writing jointly with a young engineer, who is expert on difficult mathematical work, a complete treatise on "The Designing of Steel Arch Bridges", the writer taking the chapters dealing with the economics, the specifications, and all the practical features, and his associate handling those involving the mathematics. The work had progressed only so far as the laying out of the list of chapters and the determination of the character of the contents of each, when, after thinking the matter over, the young man decided that he would not undertake the contemplated enterprise; hence it was abandoned. As the writer has neither the time nor the inclination to do, unaided, all the work on such a book, it will never be written by him, but must be left to some younger man, possibly working in conjunction with an experienced bridge designer and builder.

Mr. Sales asks what the writer means by "lateral system." The term includes all the bracing between adjacent trusses, ribs, or girders, whether lying in horizontal, vertical, or inclined planes; but excludes the cross-girders, which pertain to the "floor system." Mr. Sales is correct in his surmise that the writer assumed that "the weight of the lateral system plus rail-girders plus cross-girders will offset that in the bracing of the floor system, plus that of the rib flanges of the corresponding arch structure, plus that of the other diagonals between the arch ribs"; but the writer had indicated clearly that the weight of the vertical sway bracing between opposite columns was included with the weight of the said columns and the arch ribs, hence the word "other" excluded the diagonals of the vertical sway bracing.

Mr. Waddell.

The section in an arch rib will not often be "symmetrical about the neutral axis", for the areas of the chord members will generally be in direct proportion to the governing stress combinations. The contour of the arch rib usually cannot "be placed so as to give symmetrical rib sections"; but, for uniformly distributed loads, the axis (or line of apparent symmetry) is a parabola, while in other cases the curve should correspond to the equilibrium polygon for dead load plus one-half the live load.

Mr. Sales asks "what the author has to say" on the subject of the simultaneous existence of economy and esthetics in bridge design. More than two decades ago, the writer expressed himself thus:*

"The author is a firm believer in the principle that true economy, engineering excellence of construction, and the best architectural effect will almost invariably be found to accompany each other, and be inseparable in the designing of any bridge. Moreover, any bridge built with due consideration for, first, efficiency, second, appearance, and third, economy, will be satisfactory and gratifying to not only the trained expert, but also to the general engineer and the railroad man, and even to the public; because when an observer notes that in such a structure all the engineering requirements are properly provided for, that there is no evident waste of material, and that all due advantage has been taken of the conditions to render the bridge sightly and in harmony with its surroundings, his eye will of necessity be pleased, and his inherent sense of fitness will cause him to regard the structure with a feeling of pleasure."

Mr. Sales asks how the writer "would design the ordinary through type of truss span so that the top lateral bracing could be arranged to assist the top chords to the utmost extent by taking a part of the compression to which these members are subjected." The aiding of the top chords by the upper lateral struts is not a desirable feature, but, unfortunately, to a certain extent, it is unavoidable. In American practice such aid is reduced to a minimum by swinging the span clear from the falsework before making the final connection for each diagonal of the upper lateral system, thus preventing these diagonals from aiding at all in carrying the dead load. If it is considered advisable to reduce the amount of the aid which the diagonals give in resisting the live-load stresses in the chords, it can be done by putting a draw in them, or, in other words, by punching the connecting holes so as to shorten slightly the effective length of the piece and stretch it during erection by the use of drift-pins.

Answering Mr. Sales' question in respect to Problem No. 4, the comparisons were made with three-hinged arches; but the writer does not believe that the results would be any different for two-hinged arches. Hingeless construction for the spandrel-braced arch, although feasible under certain conditions, as far as the writer knows, has never

* In his little book "De Pontibus", p. 47.

Mr. Waddell.

been attempted or even considered. He can see no possible advantage in adopting it.

The writer is of the same opinion as Mr. Sales concerning the economies of continuous trusses, *viz.*, that the economy claimed by some engineers is due simply to an improper ignoring of the effect of reversing stresses. He has had in mind lately the solution of this question in the only satisfactory way possible, namely, the proportioning of two continuous and two non-continuous trusses for the same layout and the same live load under different specifications in respect to the treatment of reversing stresses. Owing to the fact that the calculation of stresses in long-span, continuous trusses is tedious, complicated, and expensive, the writer thought to shorten greatly the labor involved in his proposed economic investigation by procuring from a brother engineer the live-load stresses, dead-load stresses, weights of metal, etc., for a large two-span structure with continuous trusses, which that engineer had lately built; but the favor was refused. Some day, however, if the writer lives long enough, he will solve this and two other economic problems; because these three would about complete the solution by him of all the important economic questions that occur in the specialty of bridge designing.

In respect to the diagram on Fig. 16, concerning which Mr. Sales states that the writer computed the percentages for only the 100-ft. and 1 000-ft. spans and interpolated for all intermediate spans, there is a misunderstanding. The lines for both railway and highway structures were determined for a number of spans. It was the intermediate line for electric railway structures that was interpolated, owing to the fact that the writer has not built many electric railway bridges that do not carry also highway loads.

The writer certainly appreciates highly the trouble which Professor Jacoby took in preparing so much valuable information concerning metallic arch bridges to supplement his paper.

Mr. Molitor must have overlooked the last six lines of the penultimate paragraph of the paper, which read thus:

"Again, the comparison of the costs of arch superstructures and truss superstructures alone is not of much importance; for an economic investigation, to be of any value, must include both substructure and superstructure; and the costs of the former are likely to be very different in arch designs and simple-truss designs for any crossing."

It is impracticable to take the substructure into account when making general economic investigations for arch bridges, because no two case thereof are alike. In case of a succession of long spans in which there is a choice of rise, a tentative layout should be made, using the anticipated economic ratio of rise to span length when both substructure and superstructure costs are considered, then the cost of

piers and spans should be computed, the uneconomic effect of departing from the established economic ratio of rise to span length given in Figs. 1 to 4, inclusive, being used to calculate the weights of metal from those diagrammed in Figs. 17 to 21, inclusive. Next, this work should be repeated for a slightly greater ratio of rise to span length, and then for a slightly smaller ratio thereof. These three sets of computations would probably determine the best ratio; but, if not, still another set of calculations would be necessary. Mr. Waddell.

Mr. Molitor criticizes the writer's statement that "in order to cover effectively the ordinary range of span lengths for arch designing, it was necessary to compute for three lengths", saying that "it requires more than three points to fix a curve or law." In reply, the writer would state that the results of the calculations on these span lengths were not used to plot curves, but merely to show how the economics varied for different span lengths. An ample number of points was used in locating all the curves given in the paper.

Concerning Mr. Molitor's remarks on Problem No. 2, the questions he brings up are fully treated in the résumé on Mr. Fowler's discussion; but the writer would also remark that the fundamental principle of the method he originally used in determining the economic ratio of depth of rib to span length was logical, although not quite accurate enough, as was shown by the subsequently prepared, correct, detailed calculations, given previously in this closure.

Mr. Molitor thinks that "it is strange that the author did not give more attention to the economic shape of the arch center line." The reason therefor is that this economic question had already been solved satisfactorily by other investigators, including Mr. Molitor himself, the scope of the paper being only economic problems hitherto unsolved or incorrectly solved. Reference was made to this matter at one place in the paper, where it was stated that, if the dead load is practically uniform across the span, the curve should be a parabola; and that, otherwise, it should correspond to the equilibrium polygon for dead load plus half the live load.

The assumption by the writer of a single value for impact for all arch spans of the same length and subject to the same live load caused no error of any importance in the economic deductions, for the small resultant errors in the several spans compared were practically alike. Without having made a number of assumptions similar to this in unimportance, it would have been impracticable for the writer to undertake the heavy load of work involved by the entire economic investigation.

That there should be a difference in arch bridges and truss bridges, as regards the treatment of the effects of reversing stresses, the writer is not disposed to deny; for he once was compelled to design a 425-ft.

Mr. Waddell.

arch-span railroad bridge for British Columbia according to the awkward and, in many respects, absurd specifications for railroad bridges issued as standard for Canada by the Dominion Government. The writer determined first by his own specifications that the arch structure would be cheaper than a truss bridge; but, afterward, when it was detailed according to the rulings of the government specifications, the economics were reversed; nevertheless, for several good and sufficient reasons, the arch type of construction was finally adopted. Notwithstanding this fact, the writer cannot agree with Mr. Molitor in his statement that "all that can reasonably be required is to design each member so that it will withstand safely its maximum and minimum conditions of stress, one at a time, without exceeding the allowable units of stress for each condition." Such complete ignoring of stress reversion does not appear to the writer to be warranted by the present professional knowledge concerning the wearing effects of reversing stresses.

Why Mr. Molitor pins his faith to Professor Howe's ancient findings concerning the comparative economics of hingeless, two-hinged, and three-hinged arches, notwithstanding the fact that the writer has lately found, from actually computed designs and weight estimates, diametrically opposite results to those of Professor Howe, is not apparent.

No, the writer certainly is not swinging over to an approval of the use of redundant members in bridge designing; nor does anything in the paper warrant the drawing of such a conclusion.

Replying to Mr. Stoney's statement that the arch bridge is not suitable for India, because the bridges in that country are generally over sand and silt river beds, requiring very deep foundations, the writer would reply that, for such crossings, the arch is absolutely unsuitable; but, when the mountain districts of that country are developed by railroads and highways, the arch type of structure may be found to be appropriate for many proposed crossings of streams and gulches.

Supplementing Mr. Frankland's remarks on the economics of the cantilever arch, the writer would point out that the reduction of the horizontal thrusts at the tops of the piers effects a decided saving in the cost of the latter; and that the greater the proportionate lengths of the flanking spans to the arch spans, the greater the economy in pier material. As before indicated, it is impracticable, in a general study of bridge economics, to take into account the variation in costs of substructures. One could do it by passing from the general to the particular, assuming a foundation profile; but the results deduced would apply numerically to only the crossing assumed. However, they

would give a fair indication of what one might properly expect from other crossing conditions not too dissimilar. Mr. Waddell.

In the case cited by Mr. Frankland, concerning the foundations of an arch bridge being partly rock and partly piles driven to rock, his solution of the problem is perfectly proper, because the bascule separates the two types of foundation; but, as he states, the placing of one abutment of an arch span on rock and the other on piles is an unwise expedient. In the writer's opinion, so doing might, under certain conditions, involve a violation of good engineering practice.

Some engineers, who adhere to old-fashioned notions, contend that masonry or concrete arch bridges are applicable to bed-rock foundations only, and that the piers and abutments therefor should never rest on piles. Although it is true that bed-rock is the ideal foundation for such structures, pile foundations can be made entirely satisfactory, provided the masonry of the bases is carried well down into firm material capable of resisting properly the horizontal thrust. It is not legitimate to count on the horizontal resistance of the piles; and it would be criminal practice to rest the piers and abutments of an arch bridge on piles the tops of which, below the pier bases, act like stilts because of passing through soft material before reaching a hard bearing.

The writer was once the sole cause of the prevention of the building of an exceedingly long, reinforced concrete, combined railway and highway arch bridge over an arm of the sea where a great and disastrous wash-out had taken place, and in the design for which the bases of the piers and abutments were carried a very short distance below extreme low-water mark, and were supported by piles passing through 10 or 12 ft. of extremely soft material before reaching a layer of earth that had any claim to firmness. How much horizontal resistance could such stilts have offered to thrust produced by the passing of heavy locomotives? Had the structure been built on the proposed layout, an appalling accident, probably involving the loss of many human lives, would certainly have resulted; and it was only by the exertion of the writer's utmost powers of eloquence that the authorities were persuaded to reject the design. In fact, something more effective than eloquence was used; for the ignoring of a prediction of dire disaster by an acknowledged authority on bridge design would have rendered the officials concerned criminally liable in case of the occurrence of the predicted failure—and they were informed of that fact. As the writer was not retained on the work, and knew that he was not going to be, his motives were entirely altruistic; and he now has the satisfaction of feeling that the vigorous stand which he took saved the railroad companies and the community from serious trouble and the Engineering Profession in America from a lasting disgrace.

Mr. Waddell.

Mr. Frankland is quite right when he states, in respect to arch designing, that "the proper determination of the true economics calls for more judgment on the part of the designing engineer than with any other type of bridge"; and the writer trusts that the result of this paper, with the discussions and the résumé thereof, will be to enable those engineers who are considering the adoption of the arch type of construction for any crossing to come quickly to correct conclusions concerning the economics involved.

Paper No. 1427

VERIFICATION OF THE BAZIN WEIR FORMULA BY HYDRO-CHEMICAL GAUGINGS*

By Floyd A. Nagler, Jun. Am. Soc. C. E.†

With Discussion by Messrs. Clemens Herschel, David A. Molitor, Frederic P. Stearns, B. F. Groat, and Floyd A. Nagler.

Synopsis.

This paper presents the results of 23 experiments on a standard Bazin weir, 3.72 ft. high and 6.56 ft. wide. The experiments were carried on in a flume built for the University of Michigan at the Argo Spillway, Ann Arbor, Mich.

The water was measured hydro-chemically, according to the methods recommended by B. F. Groat, M. Am. Soc. C. E., in his paper entitled "Chemi-Hydrometry and Its Application to the Precise Testing of Hydro-Electric Generators."‡

Tests were made on heads as high as 4 ft. on the weir, thus extending the application of the weir formulas more than 100 per cent.

This paper describes briefly the method of hydro-chemical and weir gauging used in the experiments.

Introduction.

Volumetric experiments on the flow of water over sharp-crested weirs have been performed for only a comparatively small range in head on the weir. M. Bazin's experiments cover a range in head from 0.194 to 1.780 ft.; those of the late J. B. Francis, Past-President, Am.

* Presented at the meeting of March 6th, 1918.

† Now Assoc. M. Am. Soc. C. E.

‡ *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 951.

Soc. C. E., are included between 0.736 and 1.060 ft.; and the experiments of Messrs. Fteley and Stearns are between 0.0735 and 1.6038 ft.

These experimenters were unable to use higher heads due to the fact that their volumetric measuring basins filled too rapidly with the larger quantities of water which flowed over the weir at high heads. Nevertheless, these few experiments, within so small a range in head, were used by each experimenter in evaluating the coefficients for the standard weir formulas which bear their names.

For lack of a better basis of computation, engineers have been continually forced to apply the Bazin, Francis, and Fteley and Stearns formulas in the solution of problems involving heads on the weir many times that of the maximum on which any of these formulas are based.

Considerable might be written on the discrepancies (of as much as 3%) which exist between the three formulas for some heads of less than 2 ft.; but nothing is known of the possible differences which may exist for higher heads. Without further experiments, covering a wider range in head, these formulas cannot be applied with security in the computation of discharge in case the head falls outside those limits on which each respective formula is based.

Within the past decade the hydro-chemical method of gauging large quantities of water, originally used by some Swiss engineers, has been introduced into the United States. In 1914 Mr. Groat applied this method with considerable accuracy in testing hydro-electric generators, where quantities of water as large as 1 500 cu. ft. per sec. had to be measured. He published the results of these tests, together with an exhaustive treatment of the theory of salt-solution gauging, in his paper, "Chemi-Hydrometry and Its Application to the Precise Testing of Hydro-Electric Generators". In this paper Mr. Groat describes a method of "salt-solution gauging" for which he claims an accuracy that could only be attained by the most precise volumetric measurements. This method might easily be applied in gauging the flow of water over a weir, thus checking the existing volumetric experiments and extending the present experimental data to higher heads.

Contemplating the performance of such a set of experiments, an experimental flume was constructed at the Argo Spillway, Ann Arbor, Mich., for the University of Michigan, by the Detroit Edison Company. In the construction of this flume, it was decided to duplicate the conditions of the Bazin experiments, with additional capacity

sufficient to obtain heads on the weir (3.72 ft. high and 6.56 ft. long) as high as 4 ft. The proposed experiments could then be compared with an accepted standard weir formula and its basic experiments.

The experiments were performed between March 24th and May 2d, 1917.

Bazin's Experiments and Formula.

Bazin began his extensive weir experiments in 1886 on the Canal de Bourgogne, near Dijon, France. The weirs were constructed in a channel 6.56 ft. (2 m.) wide. Contractions were suppressed. The crest itself was made of an iron plate. Of these experiments 67 were performed on a weir 3.72 ft. high and 6.56 ft. wide, including heads up to 1.012 ft.; 38 on a weir 3.27 ft. high and 3.28 ft. long, with heads up to 1.34 ft.; and 48 on a weir 3.297 ft. high and 1.64 ft. long, including heads up to 1.780 ft. Having calibrated his standard weir within at least 1% by volumetric measurements, M. Bazin proceeded to perform experiments on weirs of different heights at places down stream in the same channel. From the results of these observations, he evaluated the coefficients for his formula. If H is the measured head on the weir, p the height of the weir, and L the length of the weir crest, then Q, the discharge in cubic feet per second, is expressed as follows:

$$Q = \left(0.405 + \frac{0.00984}{H}\right)\left(1 + 0.55\frac{H^2}{(p + H)}\right) L\, H\sqrt{2\, g\, H}$$

If the salt-solution method of gauging in the proposed experiments checks the volumetric measurements of flow over the weir throughout the range of the Bazin experiments, there is then established a basis for measuring accurately the water flowing over the weir, and the range of application of the weir formula becomes extended.

Chemi-Hydrometry.

The process of measuring the quantity of a liquid by observing the dilution that a solution of some chemical undergoes in being thoroughly mixed with that liquid, has been called "chemi-hydrometry."

For example, let 10 lb. of salt be thoroughly dissolved in a tank of water. If, on chemical analysis, it is found that each cubic foot of this water contains 1 lb. of salt, the volume of water in the tank is equal to the ratio of dilution of the salt, or 10 cu. ft. Or, suppose that a salt solution is introduced into a flowing stream at the rate of 1 cu. ft. per sec. If this salt solution contains 10 lb. of salt per cubic foot, and

it is found that each cubic foot of the flowing water, after being mixed with the salt solution, contains 1 lb. of salt, then the rate of flow of the stream is represented by the "ratio of dilution" of the salt solution, multiplied by the rate at which that solution is introduced into the stream; or, in this case, 10 cu. ft. per sec.

These examples give the essence of the theory of hydro-chemical gauging. In practice, however, other factors enter, which produce many complications. For a full treatment of errors and complications which arise, reference should be made to the paper by Mr. Groat previously mentioned. The following brief treatise on the subject is offered in order to save the reader the labor of reading and mastering that voluminous paper, since only that part of the theory is presented which will be necessary for an understanding of the methods used in these experiments. The symbols and definitions used by Mr. Groat have been adopted throughout.

In most cases the normal water contains an initial quantity of salt in solution; this must be taken into consideration, in order to make a correct gauging. Corrections must also be applied in comparing solutions of unlike temperatures. In some cases, cognizance must be taken of the fact that, when two solutions with different percentages of salt in solution are mixed, the total volume is less than the sum of the volumes of the two initial constituent solutions. This shrinkage in volume is taken into consideration by applying a coefficient, k, to the stronger solution, such that the volume of the weaker solution plus the volume of the stronger solution multiplied by k is equal to the volume of the resultant mixture.

The method of "special dilutions" and "balanced evaporations" was adopted in making the salt analysis in these tests. This method simply implies that a special dilution of the salt solution sample with the normal water sample is made in the laboratory. Effort is made to have the "ratio of dilution" of this special dilution approximate the estimated ratio of dilution during the test. This special dilution receives the same method of treatment in the laboratory as the dosed water samples.

Definitions and Equations.—The "ratio of mixture" is the ratio of the quantity of the weaker of two solutions to the quantity of the other solution with which it is mixed. It is represented by r.

The "ratio of dilution" is the ratio of the quantity resulting from the mixture of two salt solutions of different percentages to the quantity having the higher percentage. It is represented by R.

When a solution is referred to as "being of a certain percentage" it is meant that this percentage of the total weight of the solution is dry salt. It is represented by p.

By "concentration of solution" is meant the weight of chemical in solution per unit of volume. It is represented by c.

Then, let Q_1 = the quantity of water flowing in the stream;
q = the rate of discharge of the salt solution;
Q_2 = the quantity of water flowing in the stream after the introduction of the salt solution;
k = the coefficient of shrinkage of the salt solution; and
c_1, c, c_2 = the concentrations of the normal water, salt solution, and dosed flume water, respectively.

If all the solutions are at the same temperature; or, if originally at different temperatures, temperature corrections have been previously applied, then

Q_1c_1 = the weight of salt in the normal water; qc = the weight of salt in the salt solution; and Q_2c_2 = the weight of salt in the mixture.

Hence, $$Q_1c_1 + q\,c = Q_2c_2 \quad \ldots\ldots (1)$$

Also, by definition, $$Q_1 + k\,q = Q_2 \quad \ldots\ldots (2)$$

Likewise, $$\frac{Q_1}{q} = r$$

and, $$\frac{Q_2}{q} = R$$

By substitution in Equation (1)

$$rc_1 + c = Rc_2 \quad \ldots\ldots (3)$$

By substitution in Equation (2)

$$r + k = R \quad \ldots\ldots (4)$$

By substituting Equation (4) in Equation (3), we obtain,

$$rc_1 + c = rc_2 + kc_2$$

Whence, solving for r, we obtain,

$$r = \frac{c - kc_2}{c_2 - c_1} \quad \ldots\ldots (5)$$

Also, solving for c_1, we obtain,

$$c_1 = \frac{rc_2 + kc_2 - c}{r} \quad \ldots\ldots (6)$$

Equation (5) may be applied when the method of special dilutions is not used. It is applicable when the normal water, dosed water, and salt-solution sample are analyzed directly.

However, let a special dilution be made up in the laboratory, using the actual salt-solution sample with the concentration, c, and the normal pond water with the concentration, c_1. The ratios of mixture and dilution should approximate r and R, respectively, but actually have values of r' and R'. The final dilution has a concentration c'_2, approximating c_2. Then, by analogy, we may write, from Equation (6),

$$c_1 = \frac{r'c'_2 + kc'_2 - c}{r'}$$

In this equation, r must approximate r' so closely that the coefficient of shrinkage is the same for both dilutions.

Equations (6) and (7), however, may be placed equal to each other.

$$\frac{r'c'_2 + kc'_2 - c}{r'} = \frac{rc_2 + kc_2 - c}{r}$$

Solving for r, we obtain

$$r = \frac{r'}{\dfrac{c - r'c_2 - r'c'_2 - kc'_2}{c - kc_2}}$$

By analogy, from Equation (4), however, $r' = R' - k$. Substituting this value of r' in the denominator of the previous expression, we obtain

$$r = \frac{r'}{1 + R' \dfrac{c_2 - c'_2}{c - kc_2}}$$

Thus,
$$Q_1 = qr = q \frac{r'}{1 + R' \dfrac{c_2 - c'_2}{c - kc_2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

This equation is of practical application. It should be observed that c_1 has been eliminated; hence, it is unnecessary to analyze the normal pond water for its saline content. It has been stated that the use of this equation requires the previous correction of the volume of every solution handled throughout the entire laboratory process, reducing every sample analyzed in each experiment to some common temperature.

The reagent used in salt analysis is silver nitrate. This chemical is dissolved in distilled water in some standard proportions. Then a

measured quantity of this silver nitrate solution is used, sufficient to neutralize exactly all the salt in a given sample. The molecular weight of silver nitrate is 170; that of sodium chloride (common salt) is 58.5. Hence, 1 gramme of silver nitrate will neutralize $\frac{58.5}{170} = 0.3441$ grammes of salt. Thus, if the quantity of anhydrous silver nitrate contained in the silver nitrate solution used in a titration is known, the quantity of anhydrous salt contained in the sample is 0.3441 times this quantity.

If all titrations require about the same quantity of silver nitrate solution, and all samples, prepared for analysis, are of the same character and volume, and if the same quantity of indicator is used to indicate the end point of the reaction for each sample, then, for practical purposes, we may write,

$$c = \alpha\, t,$$

where t is the volume of the silver nitrate solution required to titrate a unit volume of the sample, and α is a constant dependent on the concentration of the standard silver nitrate solution, and the actual equivalent between the silver nitrate and the sodium chloride. Hence, we may write with practically (not theoretically) no error,

$$Q_1 = q\, r = q\, \frac{r'}{1 + R' \dfrac{t_2 - t'_2}{t - k\, t_2}} \qquad (9)$$

Thus, if silver nitrate of the same strength is used for all titrations in a single experiment, it becomes unnecessary to determine the actual salt content of the sample or the exact concentration of the silver nitrate solution. The values of t'_2 and t_2 have such a relation in the equation that when t'_2 approximates t_2, and there is then the same relative error in both titrations, this error has no effect on the practical value of r.

Therefore, in order to make a salt-solution test, three samples must be provided:

(1) A sample of the salt solution;
(2) A sample of the normal pond water; and,
(3) A sample of the dosed flume water.

The equation also designates that q, the rate of dosing, must be observed; and the laboratory process further involves the observation

of the temperatures of all solutions and the calibration of all flasks and pipettes, in order that r' and R' may be calculated with accuracy.

Description of Testing Plant.

Testing Flume.—The flume in which these experiments were performed was built in September, 1916, by the Detroit Edison Company. Connecting with two of the flood-gates at the Argo Spillway, it extended 143 ft. down stream.

Figs. 1 to 4 show the nature of the design and the construction of the flume.

The first 40 ft. of the flume was built 8½ ft. wide and 9 ft. deep. It then became necessary to divert it in the direction assumed by the natural flow of the river, and the remaining 103 ft. was made 6.56 ft. (2 m.) wide, the width of the Bazin channel. The lining was of 2-in., matched yellow pine, with driven splines uniting every board. No effort was made to caulk these joints or fill them with white lead. After the flume had been filled with water for three days, allowing the lining to soak and expand, there was no visible leakage at any point.

Figs. 5, 6, and 7 show the flume in process of construction, and Fig. 9 is reproduced from a photograph of the finished structure.

The quantity of water entering the flume was regulated by lowering or raising the flood-gates at the spillway. The salt solution was introduced under pressure into a sprinkling system in the orifices of these gates. Due to the fact that the water entered the flume at a very high velocity, it first became necessary to lower this abnormal velocity and distribute it uniformly over the entire flume section. This was accomplished by constructing a submerged weir 3½ ft. high across the flume at a point 16 ft. down stream from the gates. In striking this obstruction at a high velocity, the water was thrown into a great commotion, passing over the weir with a fair velocity distribution, regardless of the turbulence. This weir proved an excellent mixer for the salt solution, securing practically its uniform distribution throughout the entire flume section.

As the water passed around the bend in the flume, the velocity at the outside was observed to be perceptibly higher than that on the inside. This abnormal condition was remedied by placing sets of horizontal and vertical baffles at a point 10 ft. below the bend. The

baffles were constructed of 2-in. yellow pine boards, swinging on an eccentric longitudinal axis. By closing the vertical baffles at the right of the flume, a uniform distribution of velocities was again secured. Fig. 11 exhibits velocity contours taken at a point 25 ft. above the weir. These contours were obtained with an Ott current meter operating on a metal rod when there was a head of about 3 ft. on the weir.

Two floating railroad ties were placed across the flume about 28 ft. above the weir. These were efficient in reducing the small oscillatory wave motion of the water in the channel of approach.

The Weir.—The weir was built up of 4-in. timbers, as shown in the section on Fig. 4. The crest was formed by a $\frac{1}{8}$-in. brass strip, inserted at one edge of, and flush with one face of, a 7 by $\frac{3}{8}$-in. plate of cold-rolled steel. The brass strip was soldered and screwed to the steel plate, all recesses in the countersunk holes being filled with solder. The back face of the plate and the upper edge of the brass was then planed and finished absolutely true. This left a sharp right-angled knife-edge on the up-stream corner of the crest. The object of the brass strip was to produce a crest which would not be subject to corrosion, thus preventing the introduction of error in the weir discharge from this source. The whole plate was inserted flush with the up-stream face of the wooden timbers, and fastened to them by bolts the heads of which were countersunk in the back of the steel plate. The crest was set at an elevation of 3.72 ft. above the bottom of the flume.

Four $\frac{3}{4}$-in. bolts, 40 in. long, bound the weir timbers to the bottom of the flume. By loosening or tightening the nuts on these bolts, on either side, the weir crest was maintained absolutely level throughout the experiments.

The sides of the flume extended 6 ft. beyond the weir, but the floor extended no farther than the weir. This feature insured abundant aeration for the nappe from underneath.

The frame of the flume at the weir section was made of quadruple strength. All joints were bolted, and great care was exercised in plumbing the side posts. The timbers under the flume, at this point, rested on 4 ft. of concrete. The side posts of the frame extended for 3 ft. into the concrete. This produced a very rigid and permanent frame at the weir section. The construction is clearly shown in Fig. 4, and the erection of the frame is shown in Fig. 6.

FIG. 4.

Placing the weir at the end of the flume gave it a free basin, about 90 ft. in length. The bottom of the flume was level throughout this entire length.

Fig. 10 shows the weir with about 0.3 ft. of water flowing over the crest.

Hook-Gauges and Piezometer.—For all heads up to 2 ft., the head on the weir was measured simultaneously by three hook-gauges operating in galvanized tanks connected to the flume by 2-in. pipes. These pipes were attached so that the opening was flush with the inside wall of the flume. Heads of from 2 to 4 ft. were measured by a fourth hook-gauge. A piezometer tube, with a ¼-in. opening, flush with the side of the flume, was also read as a check on the hook-gauge measurements.

Hook-gauge No. 1 was one of the new all-metal Gurley gauges, with a 45° point. The stilling tank for this gauge was connected to a point 6 ft. from the weir and 0.414 ft. below the weir crest. This was the point of observation used by Fteley and Stearns.

Hook-gauge No. 2 was one of the old Gurley gauges, with wooden slides and a sharp needle point. The stilling tank for this gauge was connected to a point 6 ft. from the weir and 6 in. above the bottom of the flume. This was the point of observation used by Francis.

Hook-gauge No. 3 was also one of the old Gurley gauges, with wooden slides, but it was equipped with a 45° point. The stilling tank for this gauge connected to points on both sides of the flume, 16.35 ft. from the weir and 6 in. above the floor of the flume. This was the point of observation used by Bazin.

Hook-gauge No. 4 was an all-metal hook-gauge designed especially for these experiments, and made by Eberbach and Son, of Ann Arbor, Mich.; it was found to be more satisfactory in its operation than any of the four gauges used. The stilling tank for this gauge connected with the lead pipes to Gauge No. 3.

The piezometer tube was 1½ in. in diameter, with a brass scale, graduated to 0.005 ft., mounted at its side. The tube was connected with the flume at a point 11 ft. from the weir and 6 in. below the crest.

Each gauge was provided with an electric light on a drop cord in order to assist in the observation of the reflection at the point. Gauges with the 45° point were found to be the most readily observed.

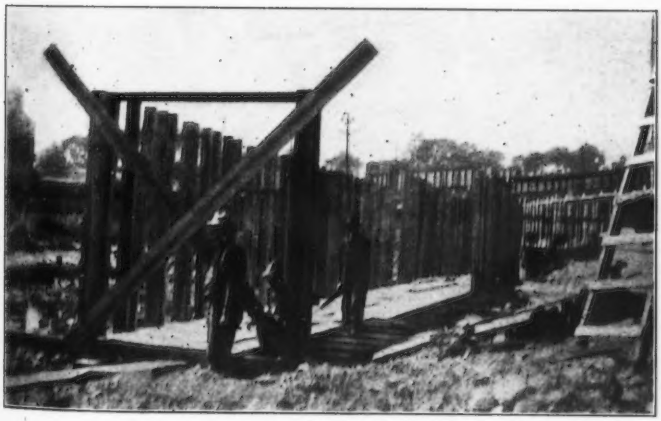

FIG. 6.—CONSTRUCTION OF FLUME.

FIG. 7.—CONSTRUCTION OF FLUME.

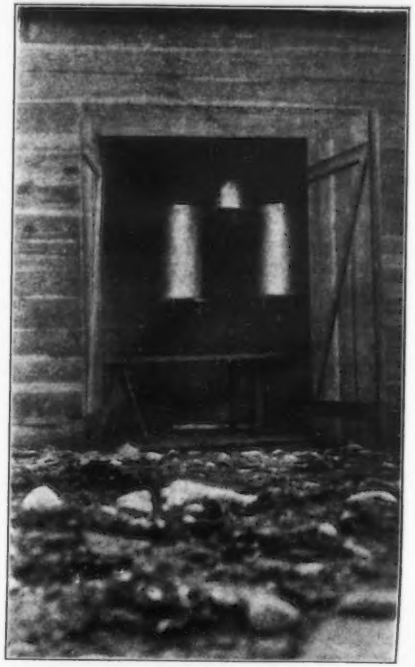

FIG. 8.—WEIR GAUGE SHELTER.

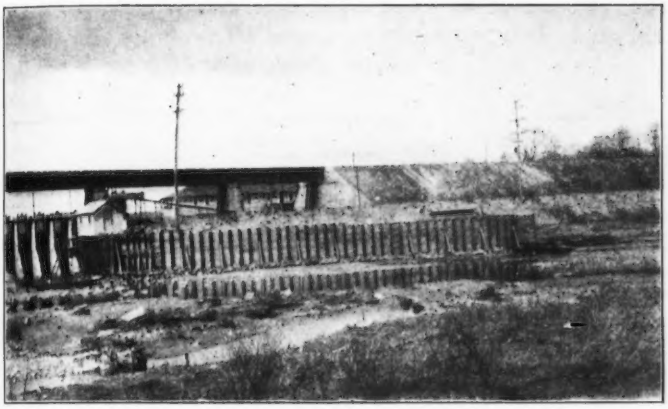

FIG. 9.—THE ARGO TESTING FLUME.

FIG. 10.—THE WEIR.

All hook-gauges were mounted on a frame of 4 by 4-in. timbers. This frame was independent of the flume, having its foundation in a mass of concrete.

The gauges were enclosed within a gauge shelter for protection. Fig. 8 shows a little of the interior of this shelter, three of the galvanized stilling tanks being plainly visible.

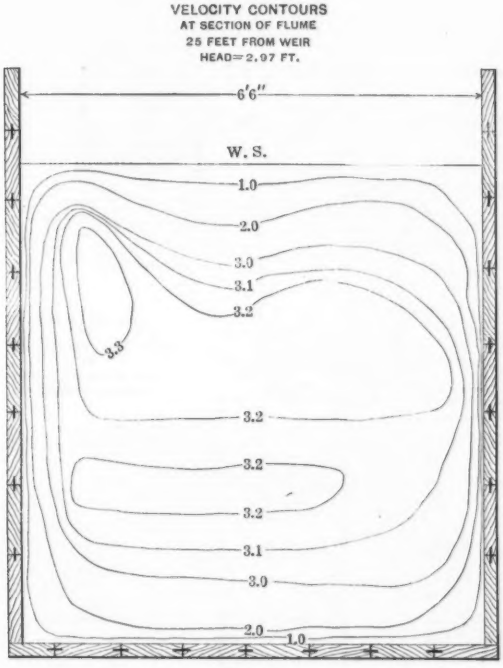

FIG. 11.

Dosing Apparatus.—In order to be able to measure a discharge over the weir as great as 200 cu. ft. per sec., by diluting a salt solution of a concentration of 300 grammes per liter, in the ratio of 6 000 to 1, during an experiment lasting 15 min., it was predetermined that a salt-solution tank with a capacity of about 50 cu. ft. would be required. This allowed 5 min. for dosing before and after each experiment, in order to insure good regulation of the dosing rate.

The solution tank is shown by Fig. 12. The tank was 4.067 by 3.33 ft. and 4 ft. deep. A piezometer was mounted on its side. The glass tube was 1 in. in diameter, and connected with the bottom of the tank. The height of the column of solution standing in the tube indicated the elevation of the solution in the tank. The gauge scale was made by Eberbach and Son. The scale had a sliding vernier

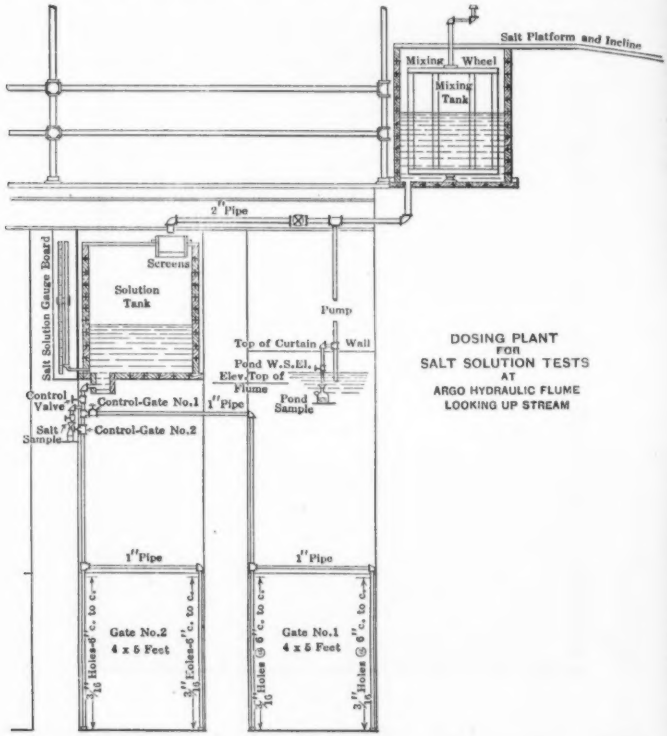

FIG. 12.

attached to a mirror index. It was possible to read the water-surface elevation within 0.001 ft. with this apparatus. Fig. 13 shows the location of the solution tank and gauge.

In varying the discharge of the water through the flume, from the least to the largest quantities, it was decided to use always the maximum quantity of salt solution which could be obtained from the

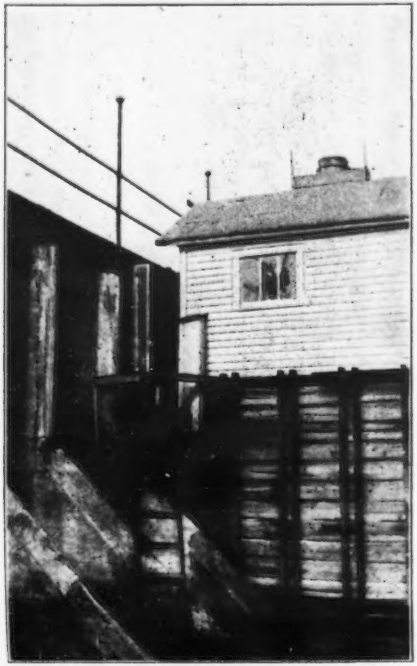

FIG. 13.—LOOKING TOWARD THE SOLUTION TANK AND PIEZOMETER.

FIG. 14.—THE CALIBRATOR.

tank. This would insure a maximum difference between the initial and final readings of the piezometer, reducing to a minimum the effect of an error in the absolute reading of the piezometer scale. Hence, an endeavor was made to maintain q approximately the same for all experiments. Consequently, in order that the flume samples from all experiments might have the same concentration, it was necessary to vary the concentration of the salt solution for each experiment. The quantity of salt used varied from 1 000 lb. for the highest, to 15 lb. for the lowest, head.

Ordinary commercial salt was used. It was found to contain some foreign matter, including small chips and fine sand. This fact, combined with the requirement that no undissolved salt be present in the solution tank, necessitated first dissolving the salt in a mixing tank and then screening off all foreign matter before passing it into the solution tank. Screens of 30 and 80 meshes to the inch were used.

The mixing tank was filled with water by the pump indicated on Fig. 12. The solution of 1 000 lb. of salt was accomplished in only 40 min. with the aid of the mixing wheel inside the mixing tank.

The rate of dosing the salt solution was maintained constant throughout the entire experiment by a general control valve. Beyond this point, provision was made for drawing off a continuous sample of the salt solution through a small pipe tapping the larger discharge pipe. The salt solution could be introduced into Gate No. 1 or Gate No. 2 in any quantity desired, by the regulation of the valves in the pipes conducting it to them.

The salt solution was introduced into the orifice under the pressure head available due to the elevation of the solution tank. Distributing pipes, 1 in. in diameter, were fastened on each side of the orifice, and $\frac{3}{16}$-in. holes, 6 in. from center to center, were drilled in these pipes at an angle of about 30° down stream. These distributing pipes, combined with the submerged weir and baffles, produced a very uniform distribution of the salt solution throughout the entire flume section.

Fig. 15 shows the general plan of the entire testing plant. The mixing tank and salt platform are in the foreground.

Sampling Apparatus.—The dosed flume-water samples were taken at a section 34.3 ft. above the weir, or 108.7 ft. from the point at which the salt solution was charged into the water.

With the flume sampling apparatus, Fig. 17, two to four samples of dosed flume water were obtained from 8 to 16 points in the flume section. Each of the inclined pipes had four $\frac{3}{64}$-in. holes drilled in the upper side, 1.64 ft. apart. The discharge through each of these small orifices was "free" and practically the same throughout the length of the pipe. The water then flowed down the inclined pipe into the sample bottle at the left. The valve at the right provided means for flushing the pipe, the pet-cock above it remaining open when the pipe was not being flushed. An excess of the sample, above the predetermined rate of 1 gal. in 15 min., for which the pet-cocks at the left were set, flowed out of the pipe through the by-pass above the pet-cock. Under any head, this excess did not exceed the sampling rate.

A sample of the normal pond water was drawn from the suction pipe of the pump, as shown by Fig. 12.

Electric Bell and Salt Detection Apparatus.—There was a 5-volt battery circuit with electric bells at the solution tank and in the gauge shelter. These bells could be heard from any point on the flume. The ringing of the bells was controlled by a push-button in the laboratory.

A salt detection circuit was established in parallel with the bell circuit. The contact points, $\frac{1}{8}$ in. apart, were inside the flume, 3.5 ft. from the bottom, at the bend, at the sampling section, and at the Bazin gauging section. A milli-voltmeter in the laboratory was connected in this circuit so that it could be placed in series with any one set of contacts. With normal water flowing through the flume, the instrument registered 15 milli-volts; but when the dosed flume water reached the contacts, the pointer would swing slowly up to 19.5 milli-volts, the salt having increased the conductivity of the water. This instrument proved invaluable in determining the time interval required by the salt to travel from the point of dosing to that of sampling. From the indications of the milli-voltmeter, the "timer" could signal the sampler when the pointer showed that a uniform regime of sale dosing had been established.

Metal Calibrator.—A heavy galvanized-iron calibrator of 4.262 cu. ft. capacity, at 10.2° cent., was used in calibrating the solution tank. The calibrator had a conical bottom and top, reducing to a

FIG. 15.—THE FLUME AND SALT-SOLUTION APPARATUS.

FIG. 16.—THE EVAPORATION APPARATUS.

1¼-in. pipe at each end. In principle, it was nothing more or less than a large pipette. Fig. 14 shows the calibrator standing in front of the laboratory, mounted on a wooden frame for convenient handling.

Chemical Laboratory.—A chemical laboratory, 8.5 by 18 ft., with sufficient equipment to make a salt solution analysis, was built on top of the flume near the spillway. Fig. 14 shows the entrance to the laboratory, and Fig 18 is a view of the inside, as seen from the door.

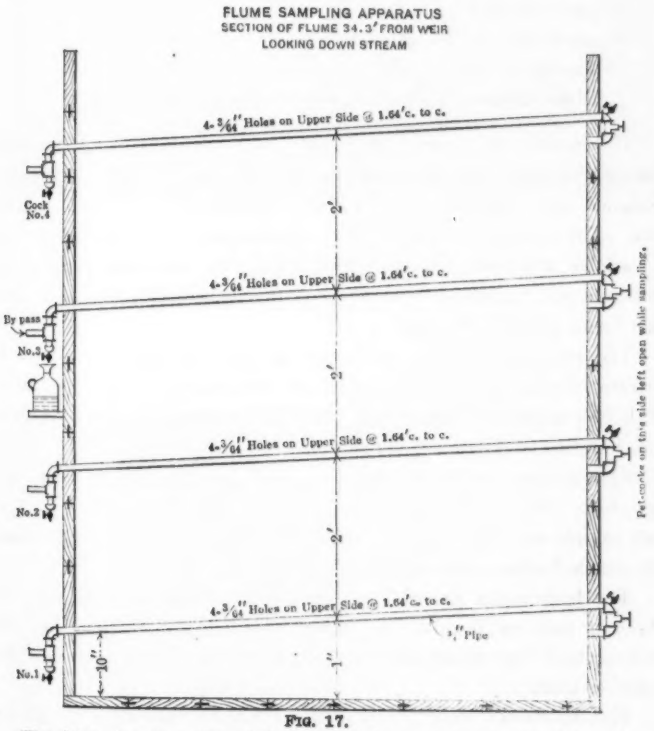

FIG. 17.

The following is a list of the essential apparatus in the laboratory:

1 balance with weights; sensitive to 0.1 mg.

1 Fairbanks scales, of 500 lb. capacity.

2 four-unit electric evaporators.

8 one-half liter separatory funnels.

4 100-cu. cm. burettes at 20° cent.
16 No. 3 casseroles.
3 one-liter volumetric flasks.
2 500-cu. cm. volumetric flasks.
1 100-cu. cm. volumetric flasks.
3 standard thermometers from 0° to 110° cent.
3 10-cu. cm. pipettes.
1 hydrometer.
12 one-liter flasks.
62 one-gallon spring-water bottles.
20 one-quart wide-mouth bottles.
Miscellaneous beakers, rubber stoppers, funnels, etc.

The separatory funnels, casseroles, and evaporators, as mounted during evaporation, are shown in Fig. 16. The evaporators were specially designed and manufactured for these experiments by Eberbach and Son. The heating coils were made of nichrome wire. By connecting a variable resistance in series with each unit, the heat under each casserole was regulated so as to keep the temperature of the sample just below the boiling point.

The experiments were performed so that the quantity of silver nitrate solution used in the titration of all samples would be either a little less or greater than 500 cu. cm. This required the use of 100-cu. cm. burettes, graduated to 0.1 cu. cm.

Spring-water bottles of 1-gal. capacity were used in obtaining the samples of the dosed flume water and the normal pond water. The salt sample was obtained in wide-mouthed 1-qt. bottles. When filled, all sample bottles were corked with rubber stoppers.

The hydrometer proved indispensable in checking the density of the salt solution in order to insure that all salt thrown into the mixing tank was dissolved before drawing the solution off into the solution tank.

The Fairbanks scales were used on top of the salt platform in weighing the salt to be dissolved.

Chemicals.—The chemicals used in the test were commercial salt, silver nitrate, and potassium bichromate.

A good grade of commercial salt was purchased at $1.43 per bbl. In these experiments, 50 bbl. were used.

FIG. 18.—INTERIOR OF LABORATORY.

FIG. 19.—TAKING FLUME SAMPLES.

Silver nitrate was used as the reagent to detect the presence of the sodium chloride. A stock solution was made by dissolving 15 grammes of chemically pure silver nitrate in a liter of distilled water. This solution was kept in a dark-colored glass bottle in a dark closet, in order to prevent action by light. This stock solution was diluted in the ratio of 10 to 1 in making the silver nitrate solution used in titration. This solution was also kept away from the light.

A potassium bichromate solution, having a concentration of 50 grammes per liter, was used to indicate the end point in the reaction of the silver nitrate on the sodium chloride. Only 6 or 7 drops of this solution were used for each titration. The indicator gives a lemon yellow color to the sample when the sodium chloride is in excess, turning to a light orange tint the instant the silver nitrate is in excess.

Hydrochloric acid proved indispensable in cleansing the casseroles after evaporation and titration. However, after cleansing, care was taken to wash away the last traces of the acid with distilled water before using the casserole for another evaporation.

Distilled water was obtained from the Chemical Laboratory of the University of Michigan. It was used in making the silver nitrate solutions, potassium bichromate solution, salt solution, sample dilutions, and in washing and cleansing the apparatus.

Method of Experimentation.

In the execution of a single experiment it was generally necessary to obtain data on the following quantities:

Salt Solution Gauging.—

(1) Dosed flume water sample;
(2) Normal pond water sample;
(3) Average salt solution sample;
(4) Average rate of dosing salt solution:
    (*a*) Quantity of solution used,
    (*b*) Duration of experiment;
(5) Temperature of flume water and salt solution.

Weir Gauging.—

(1) Average reading of the Fteley and Stearns gauge;
(2) Average reading of the Francis hook-gauge;
(3) Average reading of the Bazin hook-gauge;
(4) Average reading of the piezometer tube.

Subsequent Chemical Analysis.—

(1) Temperatures and volumes of all solutions and samples handled in the laboratory;

(2) Titration, in cubic centimeters of silver nitrate, of all samples.

In order to obtain this information, it was necessary to obtain observers to act in the following capacities:

(1) Supervising engineer,
(2) Assistant engineer,
(3) Salt solution gauge observer,
(4) Dosing valve operator,
(5) Recorder for dosing operation,
(6) Pond sampler,
(7) Timer,
(8) Flume water sampler,
(9) Observer at piezometer tube,
(10) Observer at Hook-Gauge No. 1,
(11) Observer at Hook-Gauge No. 2,
(12) Observer at Hook-Gauge No. 3,
(13) Chemist.

Duties of the Observers.—(*1*).—The duties of the supervising engineer were to outline and organize the work for the experiment, and then critically to observe its progress. By the curve sheet, Fig. 20, he knew the probable weir discharge and flume velocity for any given head on the weir. He advised the assistant engineer as to the number of pounds of salt required for the experiment, and also the specific gravity of the resultant salt solution. He advised the timer as to the probable time which it would take the salt to travel from the point of dosing to the point of sampling. He advised the chemist as to the ratio of dilution for the salt solution sample and the special dilutions.

(*2*).—The duties of the assistant engineer were to execute the experiment. He attended to the raising or lowering of the flood-gates, filling the mixing and solution tanks, and dissolving the salt. He took observations on the temperature of the flume water and salt solution; checked the timer on the duration of the experiment; and gave assistance to any observer in emergency.

(*3*).—The duties of the salt solution gauge observer were to note the readings of the piezometer tube, and thus maintain a constant rate

Period of Time Between Dosing and Sampling

FIG. 20.

of dosing throughout the entire experiment. It had been predetermined that the solution in the tank should fall 0.1 ft. in 40 sec. The observer blew a whistle when the dosing was started. He held a stop-watch in each hand; then, advancing the vernier 0.1 ft. at a time, he started one stop-watch at the same time that he stopped the other, calling off to the recorder and the valve man the number of seconds which it took the solution in the tank to fall 0.1 ft. The valve man proceeded to regulate the control valve so as to obtain and maintain the predetermined rate of flow. After good regulation had been secured, he blew a whistle as the column in the tube passed the next 0.1-ft. mark, giving the recorder the scale reading at this point. He continued to give the recorder the time which it took the salt solution to descend each successive 0.1-ft. division on the scale. After the expiration of 15 min., he ended the experiment by blowing a third whistle as the solution in the tube passed the next 0.1-ft. mark, giving the recorder the final gauge reading. The dosing, however, was continued at the same constant rate until the solution tank was emptied.

(*4*).—The duty of the dosing valve operator was either to close or open the control valve so as to maintain the predetermined salt rate. He also secured two 1-qt. samples of the salt solution continuously during the experiment, taking care to flush both the bottles and lead pipe with the salt solution before sampling.

(*5*).—The duties of the recorder were to record the observations of the initial and final scale readings and the time intervals as given him by the solution gauge observer. He also held a stop-watch from which he obtained the total duration of the experiment, starting the watch at the second whistle and stopping at the third whistle. However, the stop-watch was not relied on entirely, as its reading was always checked by observing the second-hand on an ordinary watch.

(*6*).—The pond sampler secured 1 or 2 gal. of normal pond water from the siphon in the suction pipe of the pump during the progress of the experiment.

(*7*).—The timer occupied a position in the laboratory near the bell push-button, so that he could also see the milli-volt meter indicating the presence of salt. He recorded the time of the first whistle, notifying him that dosing had begun. He then observed the time interval before his milli-voltmeter indicated that salt had arrived in any strength at the sampling section. When the salt arrived at the

sampling section in full strength, he rang a long bell. He recorded the time of the second whistle denoting that uniform salt regulation had been attained. Allowing the same period of time after the second whistle as it took the salt to arrive at the sampling section in its prescribed strength after the first whistle, he started the gauge observers reading and the flume sampler sampling by ringing two short bells. Every 20 sec. after this, he rang one short bell, signaling a simultaneous reading of all the weir gauges. He recorded the time of the third whistle indicating that the official dosing had ceased. After a time interval had elapsed, since the third whistle, equal to the time interval which it took for the salt to arrive in any strength at all at the point of sampling after it had left the point of dosing, he finally signaled the flume sampler to cease taking samples and the weir gauge observers to take their final reading. This signal was three long bells. During the entire experiment, he watched the milli-voltmeter, noting any irregularities in its behavior. He checked the difference in time between the second and third whistles with the duration of the experiment obtained by the recorder and the assistant engineer.

(*8*).—The flume water sampler cleaned out his sampling pipes with compressed air before the experiment was started. This blew all scale and sediment away from the small $\frac{3}{64}$-in. orifices. He then set the sampling pet-cocks so that the quantity discharged through them would fill a 1-gal. bottle in about 15 min. At the ringing of the long bell, he flushed out the sampling pipes and washed the sample bottles with the dosed flume water. He accomplished this as rapidly as possible and placed himself in readiness to start taking samples. He started the samples at the ringing of two short bells, finally withdrawing the bottles when three long bells signaled that the experiment had ceased. He immediately corked the sample bottles and carried them to the laboratory. Fig. 19 shows the sampler watching his samples during the progress of an experiment. The photograph was taken during high water, when the tail-water reached the elevation of the floor of the flume. This condition existed only for one week.

(*9*), (*10*), (*11*), *and* (*12*).—All weir gauge observers placed themselves in readiness to read their gauges at the ringing of the single long bell. When two short bells sounded, they took their initial reading, recording the time at which this reading was taken. They then continued to read their gauges every 20 sec., when a single short

bell signaled the reading. They took a final reading when the bell rang three successive times, recording this reading, and also the time at which it was taken.

(13).—The chemist had three classes of samples to analyze: the dosed flume water, the special dilutions, and the salt solution sample. The method of balanced evaporations required the dosed flume water and special dilutions to be evaporated and the salt solution samples to be diluted, so that final samples of similar volume of all three classes would require approximately the same quantity of silver nitrate solution in titration.

Flume samples were obtained from as many cocks as were submerged during the experiment. Three analyses were performed on each sample, to insure against error and contamination in the laboratory. As a rule, the three analyses agreed very closely and, in almost every instance, two of the three titrations checked within one-tenth of 1 per cent.

Of a flume sample, 500 cu. cm. were first measured in a volumetric flask, noting the temperature of the same. This was then discharged into a separatory funnel for evaporation. This evaporation was conducted over an electric evaporator at a temperature lower than the boiling point. An electric fan blowing the water vapors away from the casserole increased the rate of evaporation about 40 per cent. The entire 500-cu. cm. sample was evaporated until only about 10 cu. cm. remained in the casserole. Care was taken to wash the separatory funnel with distilled water and evaporate this with the rest. Each evaporation required about 7 hours, depending somewhat on the humidity of the atmosphere. The sample was then taken to the burette for titration. The initial reading of the burette was taken after the tube had been filled with silver nitrate solution to within a few cubic centimeters of the top. One drop of potassium bichromate solution was added to the initial sample, and an additional drop was added for every 10 cu. cm. of silver nitrate solution used in the titration of the sample. The silver nitrate solution was added at the rate of about 4 drops per sec., until within a few cubic centimeters of the end point of the reaction. In the meantime, a glass stirring rod was rinsed with distilled water. The final quantity of silver nitrate solution was admitted very slowly, at the rate of a drop in about 2 sec., until a point was reached where the former lemon-yellow color of the

sample was permanently replaced by a very faint tint of orange. This being the end point sought, the burette reading was recorded. The difference between the initial and final reading, multiplied by 1 000 and divided by the actual volume, in cubic centimeters, discharged by the volumetric flask when the sample was measured for titration, gave the titration per liter of dosed flume water at the laboratory temperature.

The special dilutions were treated in a similar manner. Three dilutions were made for each experiment, in order to check the laboratory processes. The ratio for a given dilution approximated that which was obtained by dividing the weir discharge (computed by formula) by the salt rate, q. In some cases, this ratio could not be attained within several per cent. with the laboratory equipment at hand.

Each dilution was made by taking 10 cu. cm., as measured by a pipette, of the actual salt solution sample obtained during the experiment, and diluting it with the proper quantity of pond water obtained during the same test, until the prescribed ratio of dilution was obtained.

In almost every experiment it was necessary to make this dilution in two steps. For example, if a dilution in the ratio of 2 500 to 1 had been desired, it would have been made up as follows:

The contents of two 10-cu. cm. pipettes were discharged into a 500-cu. cm. volumetric flask, which had been washed previously with some of the pond water sample. The flask was then filled to the 500-cu. cm. mark with the pond water sample, and inverted forty times to secure a thorough mixture of the two solutions. The temperatures of both the salt solution and the pond water were recorded. This solution then had a ratio of dilution of approximately 25 to 1. The volume of one 10-cu. cm. pipette filled with this "stock" solution was discharged into a 1 000-cu. cm. volumetric flask, which had previously been washed with some of the normal pond water sample. The flask was then filled with the normal pond water up to the 1 000-cu. cm. mark and thoroughly shaken to insure a good mixture of the two solutions. The temperature of both the stock solution and the pond sample were recorded. This mixture then had a nominal ratio of dilution of 2 500 to 1. A 500-cu. cm. sample of this dilution was measured and treated in the same manner as the dosed flume water samples.

All precautions and directions advised by Mr. Groat in his paper on "Chemi-Hydrometry" were followed strictly, in order to obtain accurate dilutions.

Dilutions of the salt solution sample with distilled water were made in a similar manner. The ratio of dilution for each experiment was obtained from Fig. 20. The contents of a 10-cu. cm. pipette filled with the dilute solution was discharged directly into a casserole, and titrated in the same manner as the other two classes of samples after evaporation.

From start to finish, the whole experiment progressed as follows:

(*1*).—The mixing tank was filled with water and the required quantity of salt dissolved in it.

(*2*).—The flood-gates were adjusted to secure the proper head on the weir.

(*3*).—The water in the solution tank, in order to keep it soaked, so that its volume would be constant, was discharged. The salt solution was then passed from the mixing tank into the solution tank by gravity.

(*4*).—The experiment was then ready to begin. The first long whistle announced that the dosing had started.

(*5*).—A long bell signaled the arrival of the salt at the sampling station. The flume sampler started to flush his pipes and bottles, and the weir gauge readers placed themselves in readiness to read their instruments.

(*6*).—The second whistle announced the fact that the prescribed uniform rate of dosing had been obtained, and that the experiment had officially begun at the dosing end. The salt solution sample and the pond sample were started at this time.

(*7*).—Two short bells signaled the flume sampler to take his flume samples, and the hook-gauge readers to take their initial readings.

(*8*).—Bells every 20 sec. signaled simultaneous readings on all the weir gauges.

(*9*).—In the meantime, the assistant engineer proceeded to take the temperature of the salt solution and the flume water.

(*10*).—A third whistle designated the end of the experiment at the dosing station. The valve man discontinued the salt sample.

(*11*).—Three bells signaled the final gauge readings. The dosed flume water samples were discontinued and carried to the laboratory.

(*12*).—The chemist then proceeded to analyze the samples.

Record Forms.—Fig. 21 displays the heads of the different forms used in recording the data obtained for these experiments.

CALIBRATIONS AND CORRECTIONS.

Stop-Watches.—The four stop-watches used in these tests were placed in the hands of a jeweler 2 months previous to the experiments, with instructions to operate and time them every day. When the experiments were started, all four watches were regulated within 1 sec. of error in 10 hours. However, subsequent regulation was found necessary, the stop-watches being timed each week during the progress of the experiments.

Two types of watches were represented: two continuous-running New England watches, and two Swiss speedway watches with cylinder movement. The New England watches gave much better satisfaction than either of those of Swiss make; but, in no experiment, was the stop-watch relied on absolutely in giving the duration of the test. The dosing recorder and also the timer kept accurate record of the time by observing the second hand on an ordinary watch. This could be read within a second. In most experiments, the three watches checked each other within a second; in such cases, the stop-watch record was used as the basis for computation.

Variation in Head on the Weir.—The experiments were performed during a period of comparatively high water in the Huron River. In no case did the pond elevation vary more than 0.05 ft. during the progress of the experiment. This insured a practically constant volume of water flowing through the flume.

The hook-gauge records, giving readings taken every 20 sec., show a maximum variation of head on the weir of 0.070 ft. for some high-head experiments. In these instances the water was traveling in the flume at a velocity exceeding 3.3 ft. per sec. With such a high velocity, the waves in the flume were of so great a magnitude that the floating railroad ties were ineffective in decreasing the amplitude of their motions. The variation decreases with a diminishing head on the weir, and, for heads below 3 ft., in no instance exceeds 0.025 ft. These variations are not due to a gradually increasing or diminishing head on the weir, but are either periodic or accidental.

The remarkable agreement between the mean readings for all three hook-gauges and the piezometer tube proves that "variation in head" was ineffective in producing error.

Fig. 21.

Determination of the Width of the Weir Crest.—Table 1 gives the results of measurements of the width between the sides of the flume for different elevations above the weir crest. The value for the width of crest used in the computations is tabulated in the last column. From top to bottom, these values do not differ more than 0.06 of 1 per cent.

TABLE 1.—WIDTH OF WEIR CREST.

4.00	6.556	6.556

Determination of the Elevation of the Weir Crest Relative to the Gauges.—In order to determine the elevation of the weir crest relative to the weir gauges, the water in the flume was lowered a fraction of an inch below the crest of the weir. A hook-gauge was then placed inside the flume, 1 ft. from the weir. By using a level, the reading of this hook-gauge when the point of the hook was at the elevation of the weir crest was ascertained and recorded. This was tested and checked for several points along the crest. The hook was then lowered to the water level, and simultaneous readings were made on this hook-gauge and those in the gauge shelter. A relation was thus established between the gauges and the weir. Two such tests were made by different observers, the results checking within 0.0001 ft. Actual levels run between the weir and the gauges checked the foregoing results within 0.001 ft. The elevation of Gauge No. 4 was established by levels run between Gauges Nos. 2 and 3. Readings from this gauge can be relied on within 0.001 ft.

Uniformity of the Mixture of the Salt Solution with Normal Water.—Table 2 shows how thoroughly the salt solution became mixed with the pond water as it passed through the flume. The distribution of

23	3.934	48.73	50.77	50.79	51.17	50.39

the mixture depended somewhat on the manner in which the flood-gates were opened. Better distribution of the salt solution could hardly be desired for all experiments up to 3.344 ft. of head. For higher heads, it was found necessary to lower the submerged weir, in order to secure the higher discharges. The resulting mixture was not as good as in the previous experiments, but only in Experiment 20 was it exceptionally bad. The excess of salt in the sample obtained from Cock No. 4 in this experiment is difficult to explain, and tends to make it less reliable by far than the others.

Calibration of the Solution Tank.—The metal calibrator was calibrated gravimetrically at different temperatures.

Starting with an empty solution tank, the contents of the calibrator were emptied into the solution tank from the spillway platform above. The solution tank gauge readings before and after emptying were recorded. The calibrator was then refilled, and the process was repeated successively until the tank was full.

Two calibrations of the solution tank were made with water at different temperatures at two different times during the progress of the experiment. These calibrations checked within 0.1 of 1 per cent.

A mean value of 1.374 cu. ft. for each 0.1 ft. of depth was used in all computations.

The solution tank was never left empty for any length of time, water being always maintained in the tank in order to insure constancy of volume. However, care was taken before each experiment to empty completely all the water from the tank and piezometer before admitting the salt solution. The tank was placed under the spillway platform and in this manner was protected at all times from the heat of the sun.

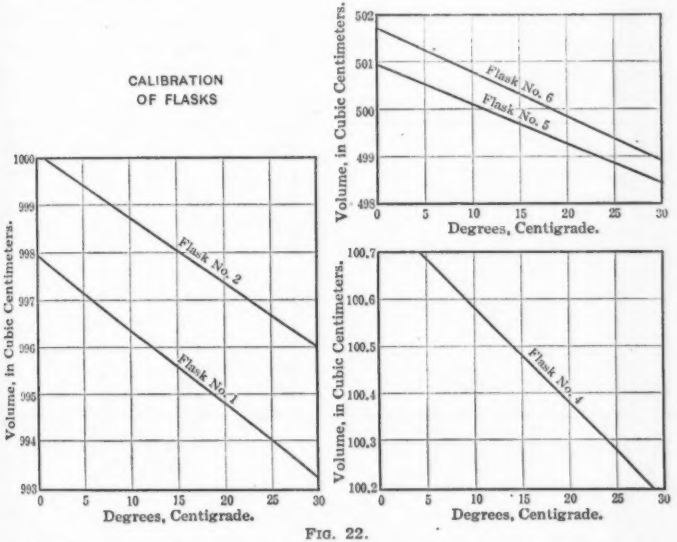

FIG. 22.

Calibration of Flasks and Pipettes.—The flasks and pipettes were carefully calibrated by R. A. Dodge, Teaching Assistant in Hydraulic Engineering, University of Michigan. Most of this work was conducted in the Physical Laboratories of the University, and the remainder on the balances at the flume.

The discharge volume of the pipettes was measured at different temperatures for different concentrations of salt solution. The flasks were calibrated at different temperatures only, using distilled water.

The results of these calibrations are represented graphically by the curves of Figs. 22 and 23. These curves were used in the final computations of the discharge by the salt solution method.

Low-Head Experiments.—For heads on the weir of less than 0.393 ft., with the apparatus at hand, it proved impossible to obtain reliable experiments, using the salt solution method. This was due to the fact that the mean flume velocity was less than 0.2 ft. per sec.; consequently, the mixing of the salt solution was poor, and the sprinkling system was not designed to meet the conditions present for so small a gate-opening.

Computation of Results.

Table 3, Plate II, gives the final computations on the data obtained in these experiments. Each step in the computation is made clear by the explanatory column at the left, designating the mathematical process involved.

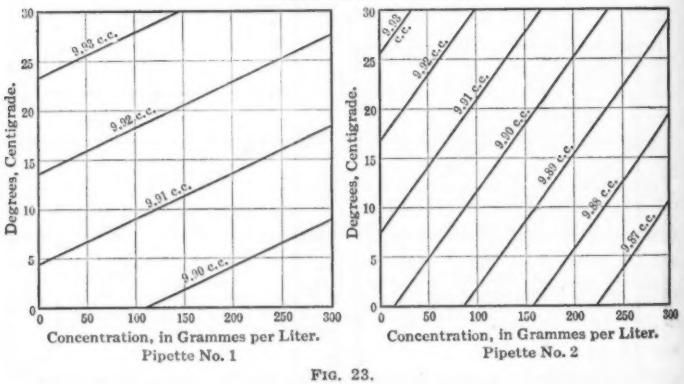

Fig. 23.

Computations were made in long hand. In general, they were carried out so that a change of one unit in the last significant figure produced a difference of less than 0.03 of 1% in the final result.

The Theiesen, Scheel, and Diesselhorst tables for distilled water, and the Landolt and Börnstein tables for solutions of sodium chloride, were used in all computations. The Williams and Hazen hydraulic tables were used in checking the weir discharge, as computed by the Bazin formula.

The shrinkage coefficient, k, did not depart far enough from unity to change the value of the last significant figure in any of the experiments. It will be noted that it has been tabulated equal to 1.0, although, for some experiments, its actual value was 0.971.

Probable Error in the Measurement of the Discharge by the Salt Solution Gaugings.

In every process of calibration, observation, and experimentation, it was sought to eliminate errors greater than 0.1 of 1 per cent. The reliability of the result for any experiment, therefore, is probably best indicated by the excellency of the distribution of the salt content of the differently dosed flume-water samples. This has been discussed, and is exhibited in Table 2.

There is no doubt that some experiments give the correct discharge within 0.1 of 1 per cent. In general, it might be said that the maximum variation from the true discharge is less than 0.6 of 1% for every experiment except No. 20. This may even be claimed for the experiments for which some of the samples are missing, due to the good distribution of the saline content for these discharges. The distribution of the salt in Experiment No. 20 is so bad that the resultant discharge can hardly be relied on within 2 per cent.

The arithmetical mean of the quantities of silver nitrate solution required to titrate the different samples was used as the value of the silver nitrate titration for the entire section. With the excellent salt and velocity distribution in most experiments, this introduced only a negligible error. In fact, due to the equal spacing of the sampling pipe perforations, the arithmetical mean was automatically taken in a horizontal direction; hence, it is doubtful whether the refinement of weighting the samples in a vertical direction is warranted.

Greater accuracy in the chemical gauging could have been attained, had it not been necessary to resort to the evaporation of the samples in making the chlorine analysis. However, the use of the direct method of analysis was prohibitive, for financial reasons, as it would have necessitated putting in a dosing apparatus of larger capacity and also the purchase of a much greater quantity of salt.

The silver nitrate solution used in the titration was as weak as it could be made and still produce accurate results; hence, further weakening of this reagent, in order to reduce the quantity of salt required in a "dosed water sample", was prohibitive. Although it is true that the experiments on the very lowest heads could have been performed with a saturated solution of salt in the existing apparatus, dosing at such a rate that the samples of dosed flume water would

FIG. 24.

require no evaporation before analysis, this could hardly be done for heads in excess of 0.4 ft. on the weir.

The ratio of evaporation used was about 50 to 1; that of dilution was about 6 000 to 1. Direct analysis of the dosed sample, therefore, would require a dilution ratio of approximately 120 to 1, with the same concentration of salt solution for each experiment as was used in these tests. Had the solution tank been of fifty times the capacity of the existing tank, the experiment on the highest head (4 ft. on the weir) could have been executed so as to necessitate no evaporation of the dosed flume water samples; but it would have required the solution of at least 20 tons of salt for the single experiment. This would be about three times as much salt as was actually used in performing the entire set of experiments. As has been previously mentioned, 50 bbl. of salt were used in these tests, costing $1.43 per bbl. Direct analysis would have required $50 \times 50 = 2\,500$ bbl., the cost of which is sufficient reason for resorting to evaporation at the sacrifice of a small degree of accuracy.

Conclusions.

Fig. 24 presents a graphical comparison of these experiments with those of Bazin on a similar weir, the Bazin experimental curve, and the Bazin formula. The weighted mean resulting curve of these experiments is shown by the dotted line. From this comparison, the following conclusions are evident:

(*1*).—For heads of less than 2 ft., the discharges, as given by the salt solution gaugings, are higher than those computed by the Bazin weir formula.

(*2*).—For heads greater than 2 ft., the Bazin formula gives discharges which are greater than those obtained in this set of experiments. This attains a maximum difference of 0.6 of 1% at a head of 4 ft. This fact is proved beyond doubt. In the future, engineers should make this correction in computations on high heads by the Bazin formula.

(*3*).—The salt solution experiments which lie within the range of the Bazin experiments, coincide with the Bazin formula and experimental curve more closely than the Bazin experiments themselves. The 67 experiments performed by Bazin on a weir 2 m. wide and 3.72 ft. high are shown by the small dots on Fig. 24.

(4).—The results of the high-head experiments fit the Bazin formula more closely than they would fit the probable extension of the Bazin experimental curve.

(5).—In claiming that the Bazin formula gives actual discharge within 1%, within the range of his experiments, this formula is all that its author maintains. There is, however, further merit for the Bazin formula, in that this statement proves to be valid for heads as high as 4 ft., on a weir 3.72 ft. high. The Bazin weir formula is thus extended 100% beyond its original legitimate field of application.

(6).—Table 3, Plate II, reveals the fact that simultaneous gauge readings on similar gauges, with similar taps, but applied at different points above the weir, do not differ by more than 0.005 ft. in extreme cases. In some experiments the readings even coincide, and, on the whole, there is no evidence of a tendency toward a definite positive or negative difference one from the other. Such differences as were actually observed might be attributed to accidental error and to the personal error of the different observers. Certainly the fact that the conducting pipe and tapping hole were 2 in. in diameter eliminated all error as to the nature of the tap.

The points at which these gauges tapped the flume duplicated the experimental points of observation used by Bazin, Fteley and Stearns, and Francis. Hence, these experiments seem to indicate that the discrepancies between the Bazin, Francis, and Fteley and Stearns formulas cannot be accounted for by the different points of observation used in their experiments. If the difference is due to the method of tapping, it must be accounted for in the nature of the tap rather than its location.

(7).—Finally, Table 4 presents a comparison between the results of these experiments and the following existing weir formulas:

Bazin, $Q = \left(0.405 + \frac{0.00984}{H}\right)\left[1 + 0.55\,\frac{h^2}{(p+h)^2}\right] L\,H\,\sqrt{2\,g\,H}.$

Fteley and Stearns, $Q = 3.31\,L\,H^{\frac{3}{2}} + 0.007\,L;\ H = h + 1.5\,\frac{v^2}{2\,g}.$

Francis, $Q = 3.33\,L\left[(D+h)^{\frac{3}{2}} - h^{\frac{3}{2}}\right].$

H. W. King, $Q = 3.34\left(1 + 0.56\,\frac{H^2}{(p+H)^2}\right) L\,H^{1.47}.$

4.00	29.833	.....	.....	30.006	+ 0.58	30.041	+ 0.70	28.416	— 4.75	29.485	— 1.17

The columns of Table 4 denoting the percentage of difference between these hydro-chemical gaugings and the other formulas, lead to the following conclusions:

(1).—The agreement with the Bazin experimental curve is remarkably good, except for the low heads.

(2).—The Bazin formula approximates these experiments within 1% for all discharges listed.

(3).—The Fteley and Stearns formula gives good results for the highest heads, but gives discharges too small for heads of less than 1 ft.

(4).—The Francis formula does not agree with these experiments. The discharges vary from 1.4 to 4.75%, and are lower than the hydro-chemical experiments, for both low and high heads on the weir.

(5).—The King weir formula approximates these experiments very closely for nearly all heads; in fact, it seems to fit the data better than any of the existing formulas, except for a divergence of 1½% at the lowest head.

Acknowledgments.

The writer is indebted to H. W. King, M. Am. Soc. C. E., Professor of Hydraulic Engineering, University of Michigan, for his assistance and co-operation in making these experiments possible. His interest in the experiments was a continual inspiration, and his suggestions were responsible for many improvements in the manner of conducting them. The writer also wishes to express his appreciation for the invaluable services of R. A. Dodge, Teaching Assistant in Hydraulic Engineering, University of Michigan. The paper by Mr. Groat on "Chemi-Hydrometry" was a constant source of reference in the execution of these experiments. Having used the methods described in this paper very freely, the writer wishes to acknowledge his indebtedness to Mr. Groat. For assistance in the operation of the experiments, the writer wishes to thank Mr. C. O. Wisler,* Instructor in Civil Engineering, University of Michigan, and the following senior and graduate civil engineering students at that University in 1917: Messrs. O. B. Apeseche,† C. E. Gill, E. R. MacLaughlin, S. P. Davis, T. G. Bedford, G. A. Covarrubias, J. B. Jewell, H. J. McFarlan, E. Gusman, T. B. Dimmick, A. H. Cohn, A. B. Pastor, J. W. Van Brunt, C. E. Wells, M. F. Wagnitz, J. B. Franks,* G. A. Pomeroy, and A. Marino.

DISCUSSION

Mr. Herschel.

CLEMENS HERSCHEL,* PAST-PRESIDENT, AM. SOC. C. E. (by letter). —Few engineers are in a position to appreciate from personal experience the amount of work involved in making the experiments necessary for writing a paper such as this, and in writing the paper itself. In every way such contributions should be encouraged, as they form steps in the advancement of engineering knowledge.

One criticism only the writer allows himself, and that relates merely to the title of the paper: In a strict sense, hydro-chemical gaugings are not competent to "verify" a weir formula. That can only be done by a tank, or volumetric gauging. The hydro-chemical method itself needs verification, by comparison with tank gaugings.

Still, an approximation to such a verification can be made, and is made when able engineers, like Mr. Groat, have first compared hydro-chemical results with those produced by weir gaugings made under their direction, themselves founded on comparisons with tank gaugings.

What the paper really presents is a "comparison" between the results of the Bazin and other weir formulas, and those deduced from hydro-chemical gaugings; both methods being in the same degree in need of verification.

And, if one pleases, even a tank gauging is not absolute. It is, for example, impossible to make a rod exactly 1 ft. long. Still less possible to mark out exactly 1 sq. ft.; less possible again, to make a cube of which each edge shall measure exactly 1 ft.; and still less possible to gauge cubic feet per second.

The title of the paper, however, does not recognize, and is likely to mislead the reader as to, distinctions of the several sorts mentioned; of value in practice and in study, even though some of them be, if one likes, of the second degree of differentiation.

With the inclusion of the discussion by Frederic P. Stearns, Past-President, Am. Soc. C. E., Mr. Nagler's paper bids fair to become as important a paper on hydraulic engineering, as has appeared in recent volumes of *Transactions*; and the author may conclude that he "has builded wiser than he knew." The very scope and title of the paper, the "verification" of a weir gauging, by a complicated process, such as a hydro-chemical gauging, no doubt caused that old-time fetish of hydraulic engineers—weir gaugings, or the "standard weir"—to totter on its pedestal; while the plain-spoken words of Mr. Stearns: "(1) That in the present state of the art the weir is not an accurate instrument for the measurement of water", and the proofs supplied by the searching analysis that follows, must have caused that old idol to fall

* New York City.

Mr. Herschel.

irretrievably from the high estate it has occupied in the minds of a numerous body of engineers, lo, these many years.

Under the circumstances, the writer has concluded that it might be of interest to hydraulic engineers were he to extend the remarks he has already made in discussion of Mr. Nagler's paper.

If one takes Fig. 26 of Mr. Stearns' discussion, it must be evident, on reflection, that an apparatus of this kind, carrying water which has a material velocity of approach, cannot cause that water to spill over the crest of the weir with a regular, or devoid-of-turbulence, motion of its particles. The velocity of approach must be changed in direction, upward and "over the top" (to use a prevalent expression of the day). If, as in truth, this velocity of approach is only the resultant in one direction of turbulent motion in all sorts of directions, but prevailing toward the weir, then such turbulence will necessarily be increased in the angle between the up-stream face of the weir and the bottom of the flume. The elements of turbulent motion are largely accidental, and hence do not lend themselves to determinations of precision.

Again, why the seemingly excruciating process of dragging the particles of water across the sharp edge of a metal right-angled corner of a bar of iron; which torture the water resists, and it protests and squirms, until it jumps upward and "over the top", in defiance of its own inclinations and the laws of gravity, so that it is forced to form a little hollow next down stream from the weir crest?

The question may be answered categorically by pointing out that 200 years ago, or more, when hydraulic experiments were in their infancy, the idea of a discharge over or through a "thin plate" was adopted for the sake of uniformity in practice—a definition of a member that could be easily stated, and the member could then be readily reproduced. Apart from this, however, it has no special value.

Suppose, instead, that we were to make a weir crest—to be adopted as the standard weir crest—semicircular in cross-section, and of some adopted standard radius of generation, say, 2.5 cm., if one likes—near enough to 1 in. to be called an inch, in the present instance; again, if one pleases, tangentially joining a solid curve of transition that shall fill the angle between the up-stream face of the weir and the bottom of the flume, somewhat following the line marked "Limit of Angle of Pressure" in Fig. 26, and, of course, to be defined in terms, to become normal (a catenary or a parabola); or a straight line, on a 2:1 slope, because it is readily constructed of wood. Would not the flow over such a weir be smoother, cleaner, less excruciating to behold or imagine? Would it not give more concordant results, and a smaller range of coefficients?

Next, let us consider the matter of observing the head on the weir. If the discharge were out of a tank, or reservoir, there would be, com-

monly speaking, no velocity of approach; and, to observe the height of still water up stream from the weir, and let it rule in the formula for discharge, would be a simple matter. This was the original condition of things, when weir experiments and experiments on the discharge of orifices were first made; when the apparatus for such experiments were mere playthings; but a weir without end contractions, near the down-stream end of a 6½ or 8-ft. flume, is quite another affair. To observe the depth on the weir in such cases, as has been generally done hitherto, is a mixing up of the study of hydrostatics and hydraulics, which long ago called forth the protest of the writer. Mr. Herschel.

This was done by an article* entitled "The New Hydraulics" ("The New Hydrometry", would have been a better title), some extracts from which may now be reproduced in this discussion:

"To the graduate student or practitioner in hydraulics [hydrometry] of the present day, there has always been something disappointing in the art. Here is a science which pretends to give rules and formulæ for the discharge of water through orifices and over weirs, when in truth it only indicates what these rules should be, and are not. Instead of being a science founded on fact, and deduced theory, as it set out to be, it has degenerated into a prolix schedule of coefficients to be applied in hydraulic cases as they are met with. So numerous have these coefficients become, that their great number has defeated their very purpose. It has been found impossible to match cases as they arise, with their appurtenant coefficients, and engineers have been obliged to practically ignore the most of them, and, instead of using them, to confine themselves in their practice to a very few selected simple cases. Instead of practicing under the guidance of a science of hydraulics, the working hydraulician takes for his mentors only a few simple hydraulic experiments, and by repeating with slavish exactness the apparatus used in the experiments to be followed, he manages merely to allow nature to do for him what she did years before for another. Any step, therefore, that will do away with or merely will reduce the range of the multitude of coefficients now found recorded in hydraulic writings for the practice of hydraulics, will benefit that science very much.

"Hydraulics, to look at the situation from another point of view, has not hitherto been able to free itself from the apron-strings of its older sister science of hydrostatics. Instead of noting the conditions obtaining strictly for the water in motion which is to be observed, and confining himself to them alone, the modern hydraulician still encumbers his work with measurements based on, or derived from, a water level which belongs in the domain of the hydrostatics of the case in hand, rather than in that of its hydraulics. Such cases are the measurement of the head on a weir, by measuring from the level of still [actually: running] water upstream from the weir; and determining the head on an orifice, from the position of the orifice and the level of still water upstream from it. Inasmuch as this mode of procedure totally eliminates the form and shape of the weir or orifice

* *Engineering News*, November 10th, 1898.

Mr. Herschel.

—takes no account of the same whatever—the measurements thus taken being precisely the same for any and all kinds of weirs and orifices; and inasmuch as these different kinds of orifices do have, nevertheless, very different unit discharges, it becomes necessary to introduce a host of coefficients to cause this method of procedure to produce the numerous called for practical results.

"But how would it be, were we in these cases to take measurements and observations which would themselves be influenced by the shapes of the orifices and by the velocity of the water passing through them? May we not hope, that the coefficients to be applied to formulæ containing data thus obtained, would have a much smaller range and would be much reduced in number, to the manifest benefit of the art and science now spoken of? * * *

"A method of doing hydraulic work in the manner alluded to must be the next great step to take in the development of practical hydraulics, and there are many signs of the times, plain enough to those who will see them, that point in the stated direction."

Bazin has left us a significant proposition in this line. On page 238 of his final essay in the *Annales des Ponts et Chaussées,* 1898, the last section of the essay and at the very end of the account of all his weir experiments, which occupied his time for 50 years,* he says:

"Pressure Under the Sheet of Water (Nappe) and Distribution of Velocity in Its Interior.—The pressure under the nappe was measured in nearly all the experiments; as also, for a certain number of them, the distribution of pressures and velocities in their interior. This distribution has a theoretical value; but not so in the case of the pressure under the nappe, which in certain cases may be utilized. Given a weir of a certain type, its coefficient, m, will depend principally on two elements, namely: the contraction at the crest, and the pressure under the nappe; this pressure being so closely dependent on the discharge, that, by observing it continuously, one could deduce from it the variations of discharge with a precision which cannot be obtained by measuring the head on the weir directly.* * *"

Bazin then goes on to show, mathematically, that the method proposed is applicable to weirs of all kinds and forms of construction:

"The measure of pressure can thus be utilized to register variable discharges. An instrument founded on that manner of procedure has been in use in America for some years to meter the discharge of large conduits. It is well known, following some experiments of Venturi, that if one constricts on a short length of conduit, its diameter, a diminution of pressure is produced, corresponding to the produced increase of velocity. Determining now, by suitable rating, the relation that exists between these two elements, it is plain that a measure of pressures will lead to a measure of discharges, and that by automatic

* Bazin's experiments on weirs are only imperfectly known in the United States. As usually quoted, they are referred to as found in the translation by Marichal and Trautwine of his article in *Annales des Ponts et Chaussées,* of 1888, II. The complete list of these articles is as follows: 1888, II; 1890, I; 1891, II; 1894, I; 1896, II; 1898, II.

registration, one obtains the discharge of the conduit during a stated time, in spite of variations of flow. On this principle is founded the apparatus devised by Mr. Clemens Herschel.* The same principle is evidently applicable to weirs, and one could even cause them to register their discharge automatically, by using the apparatus described by Engineer Hegly to translate a record of head into a record of discharge. A measure of pressures under the nappe, showing with greater sensitiveness than a measure of head, all the variations in the régime of the falling nappe, may thus render useful service in certain especial cases where great precision may be necessary." Mr. Herschel.

To resume quotations from the writer's article, previously mentioned:

"By taking heights on the weir, as measured by means of a pressure tube laid in the body of the crest of the weir [see page 217 of Bazin's article, 1898] and basing the formulæ for the discharge of weirs on such hydraulic heights, instead of on heights derived from still water, which may be called hydrostatic heights, he [Bazin] gets again, as in the experiments above recited, a much smaller range of coefficients for his formulæ. M. l'inspecteur general Bazin notes with pleasure that this mode of observation and record gives more accurate results than the hydrostatic method, and is to be followed by preference.

"Nothing is wanting, then, to enable engineers to use the method of hydraulic coefficients exclusively, except an advocacy and teaching of the practice and a collection of the new coefficients, derived from experiment."

No such work has been done, however, in the 20 years that have passed since these words were written. To some this may be a source of discouragement, or even a reflection on the cogency or validity of the suggestion made. Let one consider, however, that change and invention, in despite of all boasting on the subject, move but slowly. Engineers are fettered by the forces of inertia quite as much as other people. Old-time habits, the teachings of school books, the constraining influences of ruts and channels of thought, control them only too rigidly, or else we should long ago have seen an improvement made in the practice of hydrometry, such as has been here advocated.

Bazin, after spending the better part of a lifetime on hydraulic experimenting, leaves such advocacy as his last words to the Profession. The writer did not hesitate, 20 years ago, to argue to the same end, and 20 years of further experience has only served to confirm him in those views.

Passing now to proof that the hydraulic system of pressure observations in hydrometry, and smooth running water, lead to a small range of coefficients in the appurtenant formulas, let us consider an instrument for metering water, other liquids, and gases, that makes use of those elements of hydrometry, referring, as many readers will have at once recognized, to the Venturi meter.

* *Transactions*, Am. Soc. C. E., Vol. XVIII (1888).

Mr. Herschel.

As an advisory member of the Power Test Committee of the American Society of Mechanical Engineers, the writer has recently had the duty imposed on him of compiling the coefficients that have been found by experimenters during the some 30 years' life of the Venturi meter. These coefficients are presented in Table 5.

Explanation of Table 5.—Column 1 gives the size of the end diameters and of the throat of the meter tube; also, the nature of the test or experiment, whether volumetric (in a tank) or by comparison with a weir, and the authority for the statements made.

Column 2 refers, respectively, to the coefficients to be applied to the theoretical discharge of the Venturi tube, or of the complete Venturi meter, to attain the discharge with which it has been compared, whether tank measurement or weir. In the latter case, it does not follow that either the coefficient given, or the weir discharge from which this coefficient has been derived, is correct.

There is also given, when it has been observed, the loss of head, in feet, of water column, end to end of the meter tube.

Both coefficients and losses of head are entered as appurtenant to the velocities of water through the throat of the meter tube, in feet per second, as given in the top main horizontal row.

Columns 3 to 9 give, alternately, the coefficients and losses of head, just mentioned, according as they have been found for the complete Venturi meter, or for the meter tube only, the latter requiring an observer, notebook, and pencil, and computation or diagram, to result in knowledge of the quantity of water discharged.

Column 10 states the construction of the meter tube. It is to be understood, however, that the throat of the meter and a short section at the up-stream end are invariably made of, or lined with, bronze.

Comment appears unnecessary. Attention, however, should be called to one other feature of the general art of making measurements, revealed by the experience at Lancaster, Pa., with the Venturi meter, with tank tests, made by F. H. Shaw, M. Am. Soc. C. E., during a period of seven years. Though the average of 44 such tests differs from unity by only $\frac{1}{28}$ of 1%, yet the two extreme variations were + 1.10 and — 1.89 per cent.

Why should there be any variations as wide as this from the true average?

To ask this question, is to answer it. There is probably no simpler operation in engineering than the measurement of the length of a base line. Yet every engineer knows that, were he to measure it a thousand times, no two of the measurements would be precisely the same, except by chance, even when made by the same implements;

Mr. Herschel

Mr. Herschel.

and occasional measurements would vary materially from the true average.

The reason lies in the imperfections of human nature and abilities, in the "personal equation" and such similar defects, and not in the apparatus or method used.

Arrived at the close of this discussion, we can sum up our conclusions, by sketching how weir and orifice measurements may be made more accurate in practice and with a smaller range of discharge coefficients:

(1). Adopt, if possible by international agreement, a standard cross-section of the orifice edges, or weir crest other than a thin plate. This may be a semicircle, as has been suggested, of 2.5-cm. (1-in.) radius, being the outside surface of a 2-in. pipe, or pipe of some such diameter, in which may be fashioned the piezometer holes to transmit pressure.*

(2). Make the standard weir with a gentle channel of approach, up stream from and below the weir crest, as advocated in the beginning of this discussion.

(3). Make a series of experiments on the discharge through such orifices, and over such weirs. With the number of hydraulic laboratories happily already in being, this ought not to be a difficult matter, especially, if this experimental work were apportioned among them.

(4). Set up formulas and tables of coefficients to represent the results of these 20th Centu[illegible]draulic experiments.

Mr. Molitor.

DAVID A. MOLITOR,† M. AM. SOC. C. E. (by letter).—This paper has been read with much interest, and, as a full account of all details and observations is given, it is possible to use the results for the verification of other formulas, aside from the one chosen by the author.

It might be expected that a purely empiric formula, like that of Bazin, based on heads up to 1 ft., would still give approximately correct results up to heads of 2 ft., and the author claims to substantiate this formula up to heads of 4 ft. However, this would, at best, hold only for absolutely identical conditions and weir dimensions.

In the Cornell experiments, made in June, 1899, by the late G. W. Rafter, M. Am. Soc. C. E., with a flume 6.53 ft. wide, and a standard sharp-crested weir, 5.26 ft. high, with a range of heads from 0.7 to 6 ft. on the crest of the weir, the agreement was not as satisfactory, showing clearly the practical limitations of an empiric formula as soon as any of the principal dimensions are changed. These experi-

* Bazin used a small tube, of about 0.6-in. outer, and 0.2-in. inner, diameter, to receive the pressure from under the nappe and convey it to the measuring instrument; but this tube was laid in the body of the weir and did not constitute the crest of the weir, as is now proposed.

† Detroit, Mich.

ments* offer an exceedingly interesting comparison with the author's results. Mr. Molitor.

The Bazin formula, given by the author, contains three factors, the first of which represents the empiric coefficient generally designated by $\frac{2}{3}\,\mu$; the second factor is of irrational form, and the third represents the discharge through a lateral orifice. It is patterned after Weisbach's formula, proposed about 1844, as follows:

$$Q = \tfrac{2}{3}\,\mu\left[1.041 + 0.3693\left(\frac{H}{p+H}\right)^2\right] L\,H\,\sqrt{2\,g\,H}$$

The writer has given a general discussion† showing the incorrectness of the several formulas quoted by the author. The King formula was not previously known to the writer, but as it is theoretically the same as the Bazin formula, with slightly altered numerical constants and the exponent of H changed from $\frac{3}{2}$ to 1.47, the same objections apply, even though the apparent agreement with the author's experimental results is better than for the other formulas as shown in Table 4.

Any formula of general applicability must express the true theoretic influence of all the hydrostatic and hydrodynamic pressures and weir dimensions on the discharge. The necessity for an empiric coefficient, μ, is merely to rectify the theoretic discharge to cover the unknowable effects due to adhesion, cohesion, friction, and contraction. Such coefficients have a forced application when they are made to cover up inherent defects in a formula merely for the purpose of agreement with certain experimental data of limited scope. The mere fact that hydraulic experiments are generally confined to reasonably small cases, makes it the more necessary that the theoretic form of the formula adopted shall be rational, so as to afford some assurance of reliable results when applied to extensive weir problems such as are frequently encountered.

A keen appreciation of this circumstance prompted the writer in 1908 to publish the formulas proposed by the late Gustav Ritter von Wex.‡ These formulas served a most valuable purpose in solving the intricate problem of flow over the triple flight of locks at Gatun, on the Panama Canal, in order to supply the necessary hydraulic data for the design of the emergency dams with which the writer was intrusted during 1907-08.§

It may be of interest, therefore, in connection with this paper, to show the nature of the empiric coefficient, $\frac{2}{3}\,\mu$, as found by substituting the author's experimental data in the more rational Wex formula.

* Given on p. 82 of the writer's "Hydraulics of Rivers, Weirs and Sluices."

† Appendix A of "Hydraulics of Rivers, Weirs and Sluices."

‡ "Hydraulics of Rivers, Weirs and Sluices."

§ The solution of this problem is given in Appendix B of "Hydraulics of Rivers, Weirs and Sluices."

Mr. Molitor.

Using the author's nomenclature, Formula 22, for a uniform approach channel and vertical sharp-crested weir, becomes:

$$Q = \tfrac{2}{3}\,\mu\, L\sqrt{2\,g}\left(\frac{H}{H+\frac{p\,v^2}{g\,H}}\right)\left[\left(\frac{v^2}{2\,g}+H+\frac{p\,v^2}{g\,H}\right)^{\frac{3}{2}}-\left(\frac{v^2}{2\,g}\right)^{\frac{3}{2}}\right]\cdots(A)$$

$$\text{Where } v=\frac{Q}{L\,(p+H)}$$

$$\text{and } \tfrac{2}{3}\,\mu = 0.3818+0.05\,\frac{H}{p+H}+\frac{0.16}{H}+0.00013\,L\ldots\ldots\ldots(B)$$

Taking the author's experimental values of H and Q, as given in Table 4, also $L = 6.558$ ft. and $p = 3.72$ ft., the values of $\frac{2}{3}\,\mu$ were computed by Equation (A) and also by Equation (B), giving the results shown in Table 6.

The values of Q are 6.558 times those given in Table 4, and represent the total discharge, instead of the "discharge per foot of weir crest." It is manifestly incorrect to compute coefficients of contraction for a flow per foot of crest, for reasons clearly seen from Fig. 11, showing the distribution of velocity over the flume section and the resulting contraction adjacent to the wetted perimeter. In other words, the discharge over a weir of length, $2L$, is not equal to $2Q$, but is larger, and this difference is taken care of by the particular value of $\frac{2}{3}\,\mu$, and not by L. Where there is any appreciable end contraction, this effect becomes still more important.

TABLE 6.

H, in feet.	Q, in cubic feet per second.	$\frac{2}{3}\,\mu$ Equation (A)	$\frac{2}{3}\,\mu$ Equation (B)	Percentage of error.
0.4	5.797	0.4272	0.4275	− 0.07
0.6	10.486	0.4175	0.4162	+ 0.31
0.8	16.084	0.4117	0.4115	+ 0.05
1.0	22.402	0.4092	0.4093	− 0.03
1.2	29.550	0.4076	0.4082	− 0.14
1.4	37.440	0.4075	0.4077	− 0.05
1.7	50.556	0.4072	0.4078	− 0.14
2.0	65.108	0.4076	0.4082	− 0.14
3.0	123.330	0.4100	0.4103	− 0.07
4.0	195.645	0.4135	0.4126	+ 0.21
	Mean =	0.4119	0.4119	.....

Comparing the values of $\frac{2}{3}\,\mu$, as obtained from Equations (A) and (B), given in Table 6, it will be seen that the percentage of error is smaller in every case except the last one, when compared with the errors given by the King formula in Table 4, and the King formula fits the experiments more closely than any of the other formulas used for comparisons by the author. It should also be noted that the range in the

Mr. Molitor.

values of $\frac{2}{3}\ \mu$ for the different heads is quite small, giving a mean value of $\frac{2}{3}\ \mu = 0.4119$, while the range in the values of m in Fig. 24 is from 0.436 for $H = 0.4$ ft., to 0.4255 for $H = 0.8$ or 1.0 ft., and then increases to 0.465 for $H = 4.0$ ft.

It would seem pertinent to ask why any one should deliberately make a series of experiments to prove the correctness of a formula which is admittedly wrong in theory, and does not even fit the experiments on which it was originally based.

The experimental data from all sources certainly constitute the best scientific evidence, and when the collection of facts becomes sufficiently extensive to cover the entire range of practical application, there will be no great difficulty in establishing a rational weir formula.

The difficulty surrounding this problem is a decided shortage of facts, and not formulas. Hence, the scientific answer is to increase the assortment of facts to cover most, if not all, of the variables involved, thus reducing the element of speculation to a minimum.

In overlooking the Rafter experiments, the author evidently failed to avail himself of the best information so far given to the Profession. It might be interesting, therefore, to mention that Mr. Rafter conducted his experiments at the request of the United States Deep Waterways Commission, because the experiments and formulas given by Bazin were not deemed sufficiently wide in scope to justify their adoption in the solution of the many important questions which this Commission was required to answer. The results obtained by Mr. Rafter fully justified the views of the Commission.

A careful inspection of Fig. 24 shows quite conclusively that all experiments made on heads up to 1 ft. would lead to very erroneous conclusions when applied to heads much larger than this, and hence the high-head flows are those which must be investigated, if any valuable contribution to our knowledge on this subject is expected. As the hydro-chemical method of gauging is likely to fail on account of excessive cost and other technical difficulties regarding imperfect mixtures, etc., we must ultimately look to current-meter measurements for a final answer to large weir problems.

There can be no doubt of the high relative accuracy attainable by hydro-chemical gaugings, but whether the same degree in absolute accuracy can be secured is still to be proved.

After a careful comparison of the author's results with those of Bazin and Rafter, it appears that the discharges within the scope of actual measurements are in every case smaller than those observed by the author. This seems to indicate the presence of constant or periodic errors affecting either the author's experiments, or else all the other measurements combined.

Mr. Molitor.

Although the weighing method is no doubt inaccurate within certain limits, the errors are more likely to be of a compensating nature, and repeated measurements would tend to reduce their magnitude.

The chemical method would probably involve smaller accidental errors, but might be afflicted with more or less serious constant errors, which would not be revealed until the results are compared with those obtained from an entirely different process of gauging, such as that used by Bazin and Rafter.

For instance, the determination of chlorine by the silver nitrate titration, with chromate indicator, is permissible only in neutral solutions and in the absence of organic matter. The presence of alkalis, acids, or organic substances in the natural pond water, unless carefully allowed for, would lead to constant errors in the results. It is also possible that some of the salt solution introduced at the dosing station never reaches the sampling station and is lost by absorption in the flume walls, etc. Furthermore, the range in velocity variation on any cross-section, as shown by Fig. 11, where the head = 2.97 ft., is from 3.3 ft. per sec. down to 1 ft. next to the wetted perimeter, and may be even less than this, would affect the time of travel between the dosing and sampling stations (108.7 ft.) by from 33 to 108 sec. or more. As a matter of fact, some of the salt introduced during an experiment might not reach the weir or sampling station until long after the experiment was over. Then again, the location of the holes in the sampling pipes might not give the peripheral flow sufficient weight in the samples taken, and frictional losses in the sampling pipes might account for some retardation in the relative strength of samples. All these influences might easily account for some periodic errors, which would not necessarily be of the same sign over the entire range of the experiments (as there may be different constant errors of opposite signs) and thus account for the fundamental differences or apparently large errors disclosed between the author's gaugings and those of Bazin and Rafter.

All this would lead to the inference that it was a mistake to assume the hydro-chemical gaugings to represent the best attainable results simply because they apparently fit the Bazin formula, even though Bazin's own experiments do not agree so fully with his formula. As experiments are always more important than the formulas based thereon, the author might better seek for an explanation of the inherent differences between his own and other experimental data, and in the event that he succeeds in this, he will no doubt merit full credit for his ardent labors.

This discussion is offered with the sincere desire to assist the author in achieving such results as may be of the greatest possible value, both to himself and the Profession.

Mr. Stearns.

FREDERIC P. STEARNS,* PAST-PRESIDENT, AM. SOC. C. E.—Before discussing this paper in detail, it seems appropriate to review briefly the results of the principal weir experiments which have been made, showing, among other things, the great variation between the results obtained by different experimenters. These differences are shown graphically on the diagram (Fig. 25), which may assist to an understanding of the discussion.

In this review it is hardly necessary to go farther back than to the experiments† of the late James B. Francis, Past-President, Am. Soc. C. E., made in 1852, which introduced a new epoch in weir experiments. They were made on a large scale, with extreme accuracy, and covered a wide variety of conditions. He determined the discharge over weirs with and without end contractions, with heads on the weir ranging from 0.59 to 1.58 ft., and with varying heights of weir above the bottom of the channel.

These experiments were described in much detail, and a careful reading of the description furnishes strong evidence that everything possible was done to secure accurate results. The conditions under which they were performed were in most respects excellent. The close agreement of the deduced coefficients for each experiment with the general result of all experiments furnishes further confirmation of the accuracy of the work.

One of the first indications, based on careful tests, that a weir measurement might not be as accurate as was supposed, resulted from the experiments‡ made by Fteley and Stearns on a 5-ft. weir, in 1877. This weir in all its features was clearly well within the limitations set forth by Francis as necessary for the accurate application of his formula. The conditions for making these experiments were excellent, and most of the experiments gave results agreeing with the formula, representing them within 0.1 of 1%, but the discharges with heads on the weir corresponding to those in the experiments of Francis exceeded his by fully 0.5 of 1 per cent.

The next series of experiments was that of Fteley and Stearns, in 1879, on a 19-ft. weir, 6.55 ft. in height. These experiments were made for the purpose of calibrating the weir so that it might be used subsequently for determining the discharge through the Sudbury Aqueduct and for testing the accuracy of a current meter.

The weir was necessarily placed in a very short channel in a gate-house at the head of the aqueduct, the length of the channel from the point of a stone pier in the middle of the structure to the head wall of the aqueduct being only 8.25 ft. In order to furnish the required

* Mr. Stearns died on December 1st, 1919.

† "Lowell Hydraulic Experiments."

‡ "Description of Some Experiments on the Flow of Water Made During the Construction of Works for Conveying the Water of Sudbury River to Boston", by A. Fteley and F. P. Stearns, *Transactions*, Am. Soc. C. E., Vol. XII (1883), p. 1.

Mr. Stearns.

space below the weir for the discharge of the water, it was necessary to place the crest about 6 ft. from the end of the pier. On each side, an additional distance was available, but the lower screens were only 7.45 ft. up stream from the weir.

In view of these abnormal conditions, it was expected that the results obtained by this weir might vary considerably from those obtained

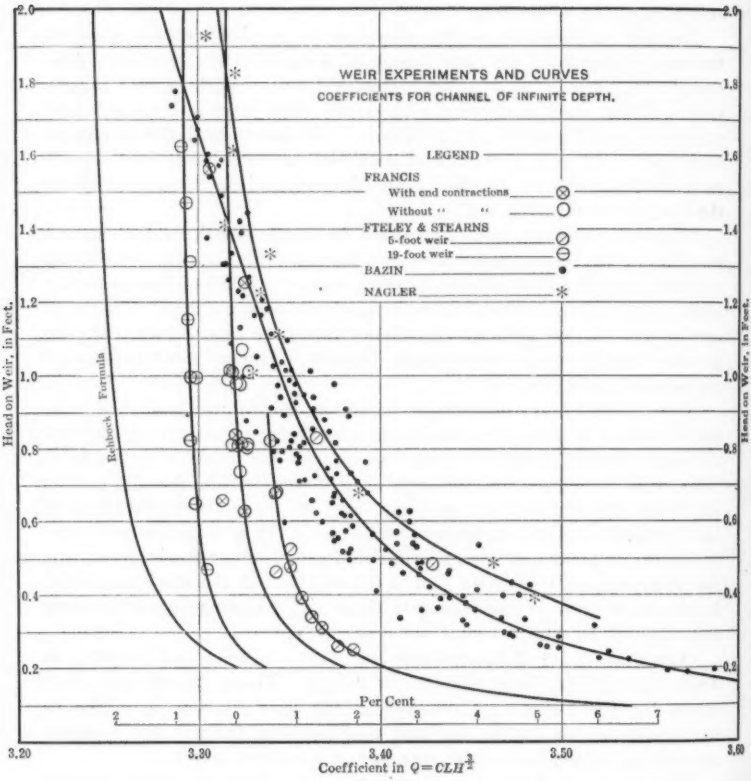

FIG. 25.

under normal conditions; but, with the smallest head covered by the experiments, the flow of water to the weir appeared to be so regular and the velocity of approach so small (0.151 ft. per sec.) that it was thought the results obtained with small heads might be normal.

The experiments produced a consistent series of coefficients for all heads on the weir, but they were about 0.7 of 1% smaller than

those determined from the experiments of Francis, and, therefore, about 1.2% smaller than those determined from the 5-ft. weir. Aside from the abnormal conditions due to the short channel, the conditions under which these experiments were made were ideal. Mr. Stearns.

The next set of experiments to cause additional doubt as to the accuracy of weir measurements was that of Bazin* on standard weirs having lengths of 6.56, 3.28, and 1.64 ft., respectively, and a height of weir above the bottom of the channel of 3.72 ft. for the first two and 3.30 ft. for the last.

These experiments were made under favorable conditions, in some respects, as the channel of approach was of good length, and there was a good measuring basin; in other respects, the conditions were unfavorable, as no provision appears to have been made for stopping oscillations or for regulating the velocities in the channel by using screens. Bazin states that, even in the stilling basin at the side of the channel, the oscillations were such that it was not feasible to determine the head on the weir by the hook-gauge alone, and he therefore used a dial operated by a float for this purpose, making comparisons, however, during an experiment, between the readings of the dial and of the hook-gauge, in order to get the proper relation to the crest of the weir.

As might be expected, under these conditions, the individual experiments do not follow closely the formula or curve representing the mean result, but the experiments are numerous, and their mean result with different heads on the weir is well indicated and consistent. This mean result agrees fairly well with the general result of the experiments of Francis when the head on the weir is about 1.5 ft., but exceeds his result by about 2% when the head is between 0.5 and 0.6 ft.

A much more recent set of experiments is that made by Th. Rehbock† in the hydraulic engineering laboratory of the Technical University in Karlsruhe. The speaker is indebted to Professor Lewis F. Moody, Consulting Engineer, for a translation of two short papers by Rehbock, describing the results of his experiments.

The experiments were carried on for several years, with an improvement in the testing outfit, from time to time, in the methods of experimenting, and in the accuracy of the observations, so that the paper of 1912 states that "the exactness of the results cannot be exceeded". In this paper, a formula is given for the discharge over standard sharp-edged weirs, with contractions suppressed.

The paper of 1913 states that it was decided to repeat the tests

Mr. Stearns.

in order to make sure that the formula of 1912 was absolutely exact, and, after making 191 additional tests, it was found that it was sufficiently correct for all practical cases except for heads on the weir less than 0.09 ft. By changing the formula slightly, it was found that it would apply correctly to smaller depths on the weir.

The experiments were on a small scale, the heads on the weir ranging from 0.03 to 0.59 ft., and the height of the crest of the weir above the bottom of the channel varying from 0.41 to 1.64 ft. The length of the standard weir was 1.64 ft., but tests were also made on a shorter weir. The individual experiments are not given; hence, in preparing the diagram (Fig. 25) only the line representing the formula could be shown.

Rehbock's results with heads on the weir of from 0.5 to 0.6 ft. are nearly 2% less than those of Francis. Hence, the inclusion of his results gives a range of experimental coefficients, obtained by different experimenters with these depths on the weir, of about 4 per cent.

Rehbock calls attention to weir experiments by Hansen, and shows their results by a diagram which indicates that Hansen's results with depths of from 0.5 to 0.6 ft. are 0.7 of 1% less than his, so that the range between Hansen and Bazin with these depths is about 4.7 per cent.

The next series of weir experiments is the one under discussion, and the precedent set by all other experimenters of obtaining results with depths on the weir of about 0.6 ft. beyond the limits reached by any previous experimenter remains unbroken. The author's results with this depth on the weir are about 2.5% greater than those of Francis, and consequently 4.5% greater than those of Rehbock, and more than 5% greater than those of Hansen. This is the present record for variation in weir coefficients with this depth on the weir, and it remains to be seen whether the next experimenter will be able to obtain results which will widen the range still farther.

In view of these large differences in the results of carefully conducted weir experiments, two conclusions seem to be warranted:

(1) That in the present state of the art the weir is not an accurate instrument for the measurement of water;
(2) That the art should be developed so that the causes of the variation in results may be discovered and eliminated.

It is much easier to ask the question, "What are the causes of these variations?" than to offer even a partial solution of the problem. The subject may be discussed profitably, even if the result is only to eliminate certain factors which are not the causes.

Notwithstanding the tendency which develops at times to accept a given weir formula and to ignore the results of others, on the ground

that they are less trustworthy, it must be clear to those who have carefully examined the descriptions of experiments which have been made, that the variations, as a rule, are not the result of inaccuracy of physical measurements, except possibly with very small heads. Mr. Stearns.

Clearly, it is not difficult to measure within a small fraction of 1% the length of a weir, the size of a measuring basin, or the interval of time required for the discharge from a weir to fill the basin if it is of sufficient size; and, as a rule, the basins have been of ample size, especially with moderate heads on the weir. The measurement of the head on the weir with a similar degree of accuracy is more difficult, but this may be accomplished, and has been accomplished even with small heads.

There is sometimes a small leakage from or into a measuring basin, but this is easily determined by observing the rate at which the water lowers before the experiment is made and after it is concluded, so that a correction practically free from error may be made.

It is customary not to empty a measuring basin completely, but to determine the volume between two water levels. In a long basin, oscillation from end to end, especially after the experiment is finished, cannot be wholly prevented, but the elevation of the water can be determined each minute for a sufficient length of time to cover one or several complete oscillations, and in this way get the correct level with minute accuracy.

As an illustration of the accuracy of such work under extreme conditions there may be cited the case of a measuring basin about 2 miles in length, where the distance between the two water levels was measured at three points with closely agreeing results. In measurements made on November 28th, 1879, the difference in level by three gauges was as follows:

Gauge	1	2.9632
"	2	2.9620
"	3	2.9582
Average		2.9611

The maximum difference from the average is 0.0029, or about 0.1 of 1%, and the average is probably still nearer the correct quantity.

An analysis of all the features of the more important weir experiments where the discharge into a basin has been measured shows that the discrepancies, except possibly those incidental to small heads, cannot be attributed to errors in physical measurements, and, therefore, their causes must be sought in the conditions under which the experiments were made.

It seems likely that the most important causes of the differences may be found in the differing motions of the water in the channel ap-

Mr. Stearns.

proaching the weir, in the manner of taking the head on the weir, and in the oscillations occurring in the surface of the water in the weir channel.

In the future much more attention than has been given in the past should be devoted to the regulation of the relative velocities of the water in different parts of the cross-section of the channel of approach, as there is some reason to believe that this is an important factor affecting the discharging capacity.

The speaker made a study of the motions of the water in the weir channel in connection with the experiments of Fteley and Stearns on the effect of velocity of approach. Where there is a long channel of approach to a weir without end contractions, the water moves forward without being affected in any way by the presence of the weir until it reaches a point distant from the weir about $2\frac{1}{2}$ times its height above the bottom of the channel; then, at the bottom of the channel, the retarding effect of the weir begins to be felt to an increasing extent as the water approaches the weir. This has been shown by measuring with a current meter the velocity of the water at the bottom of the channel at various distances from the weir.

The retardation of the current at the bottom of the channel is accompanied by an increase of pressure, so that there is in the angle between the weir and the bottom of the channel, what may be called an angle of pressure, where the head is in excess of that corresponding to the height of the surface of the water in the channel above the point where the surface curvature begins.

Fig. 26 shows the approximate limits of the angle of pressure and the extent of the pressure within it, as determined at several points when the head on the weir was 0.8047 ft., and the velocity head due to the mean velocity in the channel of approach 0.0049 ft. The figures shown are decimals of a foot, those with the plus sign showing a pressure greater than the height of the surface of the water at a point 6 ft. up stream from the weir, and those with the minus sign a pressure smaller than that 6 ft. from the weir.

The line drawn at an angle of 45° from the crest of the weir to the bottom of the channel limits approximately the triangular area in which there are irregular motions, rather than a steady current toward the weir opening, a subject which will be discussed subsequently.

It is obvious that where the bottom water is retarded there must be a corresponding acceleration of the velocity of the water at higher levels, and as there appears to be no force to cause this acceleration except that of gravity, there must be a lowering of the water surface beginning at a point vertically over the origin of the angle of pressure. The lowering at this point, however, is such a minute quantity that it is not perceptible, and it is only somewhat farther down stream that the beginning of the surface curve can be detected.

Mr. Stearns.

As the moving water approaches the weir, it necessarily mounts upward to pass over the crest, and it is natural to think of this process as occurring rather uniformly throughout the whole width of the channel. It is quite likely that this would be the case if the velocities were uniform in all parts of the cross-section, but where there is a higher velocity in one part of the width of the channel than in other parts this uniformity no longer exists.

Unless precautions are taken to prevent such action, the velocity of the water in the middle of the channel is likely to be greater than that at the sides, and, consequently, a greater pressure is produced within the angle of pressure at the middle of the channel than elsewhere. This condition cannot exist without causing lateral currents within the angle of pressure, and these in turn cause whirling motions which appear to be accelerated by the discharge of the water at the weir opening.

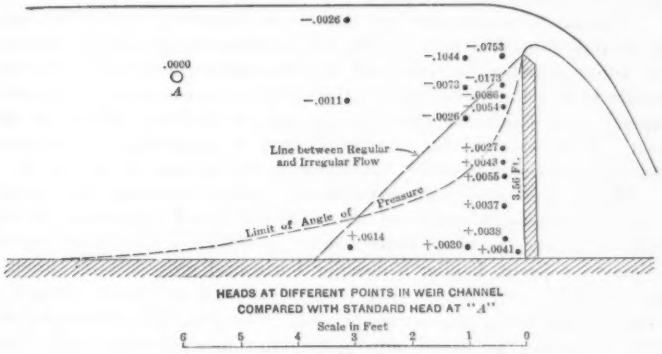

FIG. 26.

These movements may not only be deduced from theoretical considerations, but they have been observed practically. The speaker once had a small channel and weir constructed with one side of the channel of glass, for the purpose of studying these motions. The principal dimensions of the apparatus were as follows:

Width of channel and length of weir	1 ft.
Height of weir	1 "
Length of channel	8 "

A false bottom was provided by which the depth of the channel could be diminished to 0.50 ft. The motions of the water were made visible by mixing with it partly water-logged saw-dust.

There appeared to be an angle between the face of the weir and the bottom of the channel, extending up stream for about the height of

Mr. Stearns.

the weir, in which there was no regular flow. The water frequently entered this angle near the middle of the channel, reached a point near the weir, next turned horizontally toward the side of the channel, then moved upward with an accelerating spiral motion, and passed over the weir. At times the motions within this angle were very irregular.

During the experiments on the 19-ft. weir, motions in the angle above the weir, such as were observed with the weir having the glass side, evidently took place. The velocities in the middle of the channel of approach were greater than in other parts of the channel, and it was found that partly water-logged saw-dust discharged through a pipe at the foot of the weir in the middle of the channel did not pass over the central part of the weir, but all of it appeared at the ends. There was evidently a strong spiral movement in this case, as it caused a swelling of the sheet at the ends, and adjoining the swelling there was a depression of nearly equal extent.

It seems to the speaker not improbable that these movements may be an important factor in causing the variation in the results obtained by different experimenters, and that in making experiments in the future and in the application of the results of experiments to practice, special care should be taken to produce a uniform velocity in all parts of the cross-section of the channel of approach, so that these irregular movements which have been described may be minimized.

The speaker once made experiments—which impressed him deeply—as to the possible effect of these upward spiral movements at the ends of weirs. In these experiments he observed the time required to empty a basin, having a circular horizontal cross-section, through an orifice in its bottom. The first experiment was made when the water in the basin was perfectly still. The plug was removed carefully so as not to set up any motion in the water other than that caused by the discharge through the orifice.

The next experiment was made in the same manner, except that the water, before the removal of the plug, had a slight rotary motion. In this case the time required to empty the basin was just twice as great as in the first experiment, showing a very great difference in the coefficient of discharge of the same orifice as the result of what appeared in the beginning of the second experiment to be a very slight motion of the water above the orifice.

There was no velocity of approach to the orifice at the beginning of either experiment, in the sense that velocity of approach is motion in the direction of the orifice, but the slight rotary motion at the beginning of the second experiment was soon increased by the discharge through the orifice into a violent whirling motion which had a radical effect on the discharge.

Mr. Stearns.

This case seems somewhat analogous to that of the weir, except that, in one case, the motion is downward toward the orifice and in the other it is upward. The velocity of the water approaching the weir may be so small as to be practically negligible as an element directly affecting the discharge, and yet, if the velocity in one part of the channel is greater than in another, it may start spiral motions, to be augmented by the weir discharge, and thus become practically important.

The speaker believes that the view is prevalent that a very long channel of approach to a weir is a desirable feature, and that in such a case no screens would be required. This does not accord with the views here expressed. Water after flowing a long distance through a straight channel acquires very different velocities in different parts of the cross-section, the maximum velocities being in the middle of the channel and the lower velocities around the margins. Such uneven distribution of velocities, therefore, would set up secondary currents in the angle just above the weir, which are undesirable.

It is desirable, of course, to have a sufficient length of channel above a weir so that minor oscillations above the final screens may be prevented by a raft, and that screens may be provided to produce a uniform velocity throughout the cross-section at some point distant from the weir more than 2½ times its height.

An additional distance to the screens of from 10 to 20 ft. is also advantageous, in order to eliminate the minor boils and whirls resulting from the passage of water through a screen, to allow bubbles to come to the surface, and to cause the water to become level from one side of the channel to the other.

Screens should be designed with care, in order to produce the desired results. The coarse screen for equalizing the velocity in all parts of the channel should operate under a sufficient head so that the flow through its different orifices will not be materially affected by irregularities in the velocity of the approaching water. If a screen is made with vertical slats and there is considerable head, the drop of the water at the screen will cause the maximum velocity to be at the bottom of the channel. This should be guarded against, and there are many ways in which it may be done.

A free fall of the surface of the water at a screen should be avoided, in order to prevent the formation of bubbles, and for other reasons. The final screen should be fine, and preferably with diverging openings and little fall.

The place of taking the head needs consideration, the main requirement, when there is a moderate velocity of approach, being that it be taken at a place where it will not be within the angle of pressure. As a rule, there would be no harm, provided the head is measured well above the bottom, in taking it somewhat nearer the weir than the

Mr. Stearns.

upper end of this angle, say, at a distance from the weir not less than twice its height, but 6 ft. may be assumed as the minimum.

The method of taking the head is much more important. It is very rarely the case that a satisfactory measurement of the head can be made by direct measurement to the surface of the water above the weir, although the elevation of this surface is what is desired. The extended and accurate experiments of Hiram F. Mills, Hon. M. Am. Soc. C. E., on piezometers* show that "with currents flowing parallel with the side of a straight conduit, where the velocity is neither increasing nor diminishing, with orifices having edges in the plane of the side, and with passages normal thereto, the piezometric column will indicate the true height of the surface of the water in the conduit when in motion as well as when at rest." He calls attention to the necessity of attending carefully to these conditions when it is desired to obtain exact results.

The connection from the piezometric opening to the pail where the hook-gauge is placed may be made with a pipe, and, if there are no oscillations in the channel and the pipe is free from air, the water in the hook-gauge pail will stand at the same level as the surface of the water in the channel.

The speaker has tested a piezometer conforming to the requirements thus set forth, and used in connection with experiments on velocity of approach, by comparing the heads obtained with it with those obtained by direct measurement to the surface of the water, and the differences were only from 0 to 0.0003 ft. with low velocities of approach, and from 0.0003 to 0.0004 ft. with high velocities of approach.

If the water in the channel oscillates, the mean height of the water in the hook-gauge pail may be more or less than the average height of that in the channel, unless the connecting pipe and the orifices at both its ends have equal discharging capacity in both directions under a given head. For instance, if the entrance to the pipe from the hook-gauge pail were rounded, and that from the weir channel were square, and the pipe itself had equal resistance to the flow in either direction, the mean level of the water in the hook-gauge pail, as the result of oscillations, would stand lower than the mean level of the water in the channel.

It is probable that, even if the entrances to the pipe from the channel and from the hook-gauge pail are made identical, the mean level of the water in the latter may be different from the mean level of the water in the channel, by reason of the fact that the entrance to the pipe from the pail would be from quiet water, and that from

* "Experiments upon Piezometers used in Hydraulic Investigations," *Proceedings*, Am. Academy of Arts and Sciences, 1878, p. 52.

the channel would be from water flowing at right angles to the plane of the orifice. Mr. Stearns.

For the reasons stated, there can be no certainty that a correct measurement of the head will be obtained when there are oscillations in the channel.

Still one other feature needs to be considered: Mills' experiments proved that accurate measurements of the height of water in a channel may be obtained by using piezometers which comply accurately with his requirements when the water is flowing at a constant elevation, so that the pipe leading from the orifice to the gauging basin transmits pressure and does not cause a current through the pipe. If there are oscillations, there is necessarily a discharge into or from the orifice, and there is no evidence that, under these circumstances, the piezometric measurement will be correct. It is not difficult to prevent oscillations or to reduce them to extremely small amounts, except where they are caused by the wind, and the effects of the wind can be avoided by housing the apparatus.

When gaugings are to be made by the hydro-chemical method, it may not be feasible to suppress oscillations without at the same time suppressing the agitation and turbulence that are necessary for the thorough mixing of the salt solution with the water in the channel.

In order that, in the future, results may be produced which are consistent with one another and capable of reproduction at other weirs, the speaker submits the following as some of the conditions which should be observed:

1.—The weir should be one with end contractions suppressed. This is the general practice at the present time.

2.—A basin should be provided for measuring the water discharged by the weir, as this is the simplest and most accurate method of determining the volume.

3.—The weir channel should have sufficient depth, so that the velocity of approach will at all times be small.

4.—The weir and channel should be covered, and protected from disturbance by the wind.

5.—Arrangements should be made for a uniform flow, free from oscillations.

6.—Minor oscillations should be prevented by a raft above the screens.

7.—Care should be taken to produce an equal velocity in all parts of the weir channel. Current-meter measurements of the velocities in different parts of the channel should be made and recorded, and the screens should be modified until uniformity is attained.

8.—Piezometers should be provided on both sides of the channel, connected with separate hook-gauges. These piezometers

Mr. Stearns.

should conform with the requirements set forth by Mr. Mills. In the case of very wide channels, one or more additional piezometers may be required in the central portion of the channel.

9.—It is desirable that observations be made of the head in the angle at the foot of the weir, to determine whether the excess of head in this angle is normal; and other tests should be made in order to determine the movements of water in the angle up stream from the weir.

Coming now to a more direct discussion of Mr. Nagler's paper, the speaker appreciates the high degree of skill which has been displayed by the author in obtaining such consistent results in weir measurements by the hydro-chemical method. It is surprising that such uniform results could be obtained where so many different volumetric and chemical determinations were necessary.

Looking at the subject broadly, the speaker believes that, where the most accurate results obtainable are desired in the measurement of water over weirs at the present time, it is best to use a formula based on the results obtained by various experimenters rather than one deduced from any one set of experiments; and as this represents his idea of the most accurate results obtainable with present information, he obviously does not accept new results which for moderate heads on the weir are greater than those obtained by any other experimenter.

As has already been stated, the variation in the results obtained by different experimenters appears to be due to the conditions, known and unknown, under which the particular experiments were made, and, judging from the high discharge over the author's weir with moderate heads, the conditions in his case were especially unfavorable.

In order to compare the author's results with others, the speaker has recomputed them, after correcting the depths for the effect of velocity of approach, and in this way has obtained the corresponding coefficients for a weir of infinite height—or, in other words, for a weir in which the velocity of approach is negligible.

This correction has been made, not by applying Bazin's general formula for the discharge over weirs, which is quoted by the author, but by using the formula directly determined by Bazin from his experiments with weirs of different heights. According to this formula the observed head on the weir is corrected for velocity of approach by adding $1\frac{3}{4}$ times the head due to the mean velocity of the water in the weir channel. The coefficient, $1\frac{3}{4}$, is a generalization by Bazin of varying coefficients found with different heights of weirs and different heads on the weirs. Fteley and Stearns, as the result of

Mr. Stearns.

their experiments on velocity of approach, adopted 1.5 as a general coefficient in the same formula.

After recomputing the results of the author's experiments in the manner indicated, so as to make them comparable with those obtained by others, it is found that with the smaller heads on the weir, ranging from 0.4 to 0.7 ft., his results are somewhat above those of Bazin, which, in turn, are considerably above those of all other experimenters. With a head on the weir of about 1.6 ft., the results agree well with those of Francis, Fteley and Stearns, and Bazin. With heads of about 4 ft. no comparisons can be made, because other experimenters have not dealt with such large heads, but the speaker believes that those experiments with very high heads have little general value, because of the high velocity of the water in the channel of approach.

The effect of velocity of approach on the discharge over weirs has been determined experimentally by causing the same quantity of water to flow over weirs of different heights and noting the effect on the head on the weir. In the extreme case in Bazin's experiments, the maximum effect was 0.144 ft. on a weir 0.80 ft. high; in the extreme case in the Fteley-Stearns experiments, 0.128 ft. on a weir 0.50 ft. high. Using the Bazin formula, the effect of velocity of approach in the author's experiment with maximum head would be 0.377 ft. on a weir 3.72 ft. high.

In most practical cases the difference in the effect of velocity of approach by the formulas of Bazin and of Fteley and Stearns is unimportant, but, as applied to the maximum experiment of the author, it amounts to a difference of 0.038 ft., which would affect the discharge by about 1½ per cent.

The author suggests that his experiments with large heads verify Bazin's formula for these greater heads, but, even if this were the case for a weir 3.72 ft. high, it would not verify the formula for other heights of weir, unless that part of the formula which takes account of the effect of the velocity of approach is strictly correct, and, because of the arguments above stated, there is no reason to think that any formula for velocity of approach can be depended on so far beyond the limits of actual experiment.

In regard to the coefficients in the weir formula for high heads, it may be said that experiments with orifices and nozzles show that the law that the discharge varies as the square root of the head is applicable to very high heads, and the same principle is involved in the weir formula when the heads are not small and the discharge is not affected by velocity of approach. Hence, one may reasonably, and probably without any serious error, use for a head of 4 ft. the coefficient deduced from experiments with a head of 1.5 ft. The uncertainty in practice arises more from the effect of velocity of approach, and it is the formula for making this correction that is

Mr. Stearns.

especially important when dealing with high heads in cases where a great depth of channel cannot be obtained.

Attention is again called to Fig. 25, which shows the results obtained by different experimenters, after eliminating the effect of velocity of approach, so that the coefficients are applicable to a channel of infinite depth.

When Francis made his correction for velocity of approach, no trustworthy experiments had been made to determine the amount of such correction, and, consequently, he adopted a correction, based mainly on theoretical considerations, which gave satisfactory results with his experiments, in which the effect of velocity of approach was small.

Since that time, however, experiments by Fteley and Stearns and by Bazin show definitely that velocity of approach has greater effect than is indicated by the Francis formula. His experiments, therefore, have been recomputed, with larger corrections for velocity of approach than he used, and the diagram is based on the corrected results. The curve representing the mean result of his experiments as recomputed, was determined by the formula, $Q = 3.313\ L\ H^{\frac{3}{2}} + 0.006\ L$. This is a substitute for the Francis formula for suppressed weirs, which, for a channel of infinite depth, is $Q = 3.33\ L\ H^{\frac{3}{2}}$.

When the latter formula is used, the correction for velocity of approach should be that given by Francis, which is substantially an addition to the measured head on the weir of the head due to the mean velocity of the water in the channel of approach; but, if the revised formula is used, the addition to the measured head should be substantially 50% greater.

The curve representing the Fteley and Stearns experiments on the 5-ft. weir was computed from the formula, $Q = 3.33\ L\ H^{\frac{3}{2}} + 0.0065\ L$; that representing their experiments on the 19-ft. weir from the formula, $Q = 3.291\ L\ H^{\frac{3}{2}} + 0.004\ L$.

The Rehbock formula for a channel of infinite depth is

$$Q = \left(3.235 + \frac{0.0167}{H - 0.0094}\right) L\ H^{\frac{3}{2}}.$$

The curve representing Bazin's experiments is his experimental curve, and not one computed from his formula, which does not agree as well with his experiments.

The Nagler curve is one representing his experiments after they have been corrected for velocity of approach.

It is not the speaker's purpose in this discussion to pass on the merits of the different series of experiments, but it does not seem out of place to call attention to a prominent feature of the diagram,

Mr. Stearns.

namely, that the experiments of Francis, Fteley and Stearns, and Rehbock, with the larger heads on the weir—say, those above 1 ft.—give coefficients which change very little with increasing heads. In this respect, they seem to be in harmony with the well-established principle, already referred to, that velocities vary as the square root of the head, except when the heads are small. With small heads and the consequent low velocities, such factors as the cohesion and viscosity of the water and its adhesion to the edge of the weir have a very much more important effect on the discharge than with large heads and high velocities.

Bazin's experiments, on the other hand, show rapidly decreasing coefficients as the heads increase, and, even with the larger heads on the weir, this marked decrease in the size of the coefficient continues.

Francis made a series of weir experiments at the Tremont turbine,* entirely separate from those on which his formula for the discharge over weirs was based, in which a constant volume of water was discharged over weirs of different lengths, and these experiments may be used to test the rate at which coefficients increase with decreasing heads on the weir.

These experiments were made with weirs having end contractions, and the conditions for maintaining an exactly constant volume of water over the weirs were not very favorable, as there was a somewhat variable head acting on the orifices through which the water was discharged; but the experiments were conducted with much care, and due account was taken of the variations in the head on the orifices.

By selecting only the experiments in which the discharge was least influenced by end contractions, results may be obtained which, though not conclusive, will indicate whether or not, within the range of the experiments, the experimental formula or curve tested gives coefficients increasing too much or too little with decreasing heads on the weir. Corrections for end contractions were made by using the rule subsequently adopted by Francis, namely, the reduction of the measured length of the weir by one-tenth of the head on it for each end contraction.

As the volume of water in these experiments was practically constant, the head on the shorter weir is obviously greater than that on the longer weir. If, therefore, one assumes the coefficient for the head on the shorter weir to be that given by any particular weir formula or curve, he may compute the corresponding coefficient for the smaller head on the longer weir. If this coefficient is larger than the coefficient for the smaller head, as deduced from the weir formula or curve under consideration, it furnishes an indication that the

* "Lowell Hydraulic Experiments," p. 88.

Mr. Stearns.

coefficients in the formula or curve do not increase fast enough, and, if the coefficient is smaller, the indication is reversed.

The weir formulas or curves which may well be compared, because the experiments on which they are based conform most nearly to the range of heads in the Francis experiments at the Tremont turbine, are those of Fteley and Stearns for the 5-ft. weir, Bazin, and Rehbock.

By referring to Column 13 of Table 7 it will be seen that the differences of the experimental coefficient for the smaller heads from that by formula or curve are always plus in the case of the Fteley and Stearns formula for the 5-ft. weir, and practically the same statement may be made as to the differences in the case of the Rehbock formula. On the other hand, the differences in the case of the Bazin experimental curve are always minus. The average difference in the case of the Rehbock formula is + 0.34 of 1%, Fteley and Stearns formula, + 0.44 of 1%, and the Bazin experimental curve, — 1.11 per cent. In other words, the coefficients in the Rehbock and Fteley and Stearns formulas do not increase quite as rapidly with decreasing depths on the weir as is indicated by these experiments, and in the case of the Bazin experimental curve they increase more rapidly.

There are in this paper, and especially in the introductory portion, statements of a historical nature which are inaccurate. Thus, the author speaks of the experiments of Francis as covering a range in head on the weir of from 0.736 to 1.060 ft., whereas these experiments covered a range of from 0.592 to 1.569 ft.

In the next paragraph, referring to several experimenters, he says that they were unable to use higher heads, due to the fact that their volumetric measuring basins filled too rapidly with the large quantity of water which flowed over the weir at high heads. The Fteley and Stearns experiments were included in this statement. There was no such limitation in the experiments with the 19-ft. weir. With the maximum discharge, the basin filled in about 36 min.; it may be noted that the author discharged his volumetric tank containing the salt solution in about 15 min.

In the same paragraph he adds: "Nevertheless, these few experiments, within so small a range in head, were used by each experimenter in evaluating the coefficients for the standard weir formulas which bear their names." This statement is somewhat incorrect, because the Fteley and Stearns general weir formula, where it relates to heads of more than 0.5 ft., was based almost wholly on the experiments by Francis. However, the formula was given a form which would make it agree with these results of Francis and with those obtained by Fteley and Stearns with small heads on the weir, thus making a formula of more general application than that of Francis, which was not applicable to small heads on the weir.

Mr. Stearns.

The author seems to suggest in his statement that a few experiments are not a sufficient basis for a formula, but this depends on the accuracy of such experiments. A reference to those on the 19-ft. weir by Fteley and Stearns, as represented by Fig. 25, shows clearly that the line representing them is practically as well determined by the number of experiments made as if they were multiplied many times.

He states, on page 154, that the points at which the gauges which he used tapped the flume duplicated the experimental points of observation used by Bazin, Fteley and Stearns, and Francis. Hence, his experiments seem to indicate that the discrepancies between the Bazin, Francis, and Fteley and Stearns formulas cannot be accounted for by the different points of observation used in their experiments.

In order to duplicate the Fteley and Stearns points of observation, he connected the stilling tank to the side of the channel 6 ft. from the weir, and 0.414 ft. below the weir crest. In the experiments on the 5-ft. weir of Fteley and Stearns, the head was taken about 1 ft. above the bottom of the channel, 6 ft. up stream from the weir, at a point in the channel 1.5 ft. from its side. In the experiments on the 19-ft. weir of Fteley and Stearns, the heads were taken through four double piezometers, each in the middle of a fourth part of the width of the channel, just below the level of the crest of the weir.

To represent the point of observation used by Francis in experiments on suppressed weirs, the author connected the stilling tank with the side of the flume at a point 6 ft. from the weir and 3.22 ft. below the crest. Francis took his observations in the middle of the channel at a point 6 ft. from the weir and 4.80 ft. below the crest. The difference in this case is important, because the head as taken by the author was probably outside the angle of increased pressure, and the head taken by Francis was within the angle of pressure, but not where the increased pressure was great. This was demonstrated in the case of the Francis experiments, because he found by test that the head at the point chosen, 6 ft. from the weir, was greater than the head 12 ft. from the weir. In the Francis experiments, however, the velocities were so low that the point of taking the head did not have much importance.

The author is rather optimistic about a number of features connected with the experiments. Thus, on page 154, in discussing the method of taking the head on the weir, he says: "Certainly the fact that the conducting pipe and tapping hole were 2 in. in diameter eliminated all error as to the nature of the tap." It would be rather interesting to know why the use of a pipe and tapping hole of a given diameter should eliminate error. He gives no information as to whether the taps complied with those features which Mills, from his experiments on piezometers, found necessary, namely, as to whether

the orifice was precisely in the plane of the side of the flume, and whether the pipe was precisely normal thereto. Mr. Stearns.

He says elsewhere in the paper that when the water in the flume had a velocity exceeding 3.3 ft. per sec. "the waves * * * were of so great a magnitude that the floating railroad ties were ineffective in decreasing the amplitude of their motions." With such oscillations, it would seem quite possible, for reasons already suggested, to record a head at the hook-gauges which was not the true head on the weir, notwithstanding what he refers to as "the remarkable agreement between the mean readings for all three hook-gauges and the piezometer tube."

The author speaks in one place of the excellent velocity distribution in most experiments, and, on page 125, presents velocity contours at a point 25 ft. above the weir, which show something far different from a uniform distribution, as the velocities range from less than 1 ft. per sec. near the surface to 3.2 ft. per sec. at mid-depth. The low velocity at the surface may have been due to the floating railroad ties a short distance above this section, and the conditions nearer the weir may have been more favorable.

On page 118, the statement is made that placing the weir at the end of the flume gave it a free basin about 90 ft. in length, which does not seem to agree with the statement that there were two floating railroad ties placed across the flume about 28 ft. above the weir.

It is rather interesting to note the optimistic conclusions of the experimenters who have obtained especially low and high results. Thus, Rehbock, who experimented with heads on the weir ranging from 0.03 to 0.59 ft., referring to the degree of accuracy of his formula, stated that he was convinced that the results to be obtained by it deviated not more than ½ of 1% from the true value.

The author, with results that are about 4.5% higher than those obtained by Rehbock, says: "There is no doubt that some experiments give the correct discharge within 0.1 of 1 per cent. In general, it might be said that the maximum variation from the true discharge is less than 0.6 of 1% for every experiment except No. 20."

B. F. Groat,* M. Am. Soc. C. E. (by letter).—Mr. Herschel gives some valuable suggestions as to weir coefficients. The writer adds that, perhaps, a correct application of the theory of similarity† may further simplify the question for geometrically similar weirs with proportional heads, provided the latter are not too small. Mr. Groat.

It should be observed, however, that to have exact similarity, under

* Pittsburgh, Pa.

† "Ice Diversion, Hydraulic Models, and Hydraulic Similarity", *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1138.

Mr. Groat. given gravitational forces, the model weir should be tested with a different fluid from that discharged by the prototype. As an example, a weir about one-sixth of full size might be tested with mercury at a proper temperature. This calls attention to the fact that temperature observations have been omitted too frequently in the past.

In referring to the dynamic reactions of different fluids, it should be borne in mind that the same fluid under different viscosity conditions (as water at different temperatures) acts exactly as so many different fluids. Weirs under low heads are certainly very sensitive to changes in viscosity and, therefore, to changes of temperature.

Mr. Nagler. FLOYD A. NAGLER,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer had not intended to enter into a discussion comparing the results of all weir experiments with his own hydro-chemical gaugings. Engineering literature has worn this subject practically threadbare. In verifying the Bazin results, the hydro-chemical gaugings naturally differed from the conclusions of other experimenters; but the main intent of the paper was to offer a new set of experiments which, having been executed, was found to check with the formula for discharge of weirs, which Bazin deduced from his studies, far beyond the actual range in head of the Bazin experiments.

With the contribution to engineering practice of such valuable work as that performed by B. F. Groat, M. Am. Soc. C. E.,† the hydro-chemical method of measuring water becomes quite as reliable as any so-called "tank" or volumetric process when conducted with an equal degree of skill and care. In fact, the hydro-chemical method is a volumetric process and depends on the accurate measurement of quantities of solution; and the chemist can determine the number of parts of chlorine or other element in a given quantity of water with as great refinement and ease as the engineer can measure a base line. This hydro-chemical method, therefore, becomes compatible with any other volumetric process for measuring water in an effort to determine weir coefficients or check weir formulas. In neither case can exact values be obtained, but the truth is revealed in proportion to the accuracy, range, and square root of the number of measurements; and, thus, a sufficiently great number of experiments constitute an adequate basis for the "verification of any formula," or even the evolution of the formula itself.

The writer has mentioned that the experiments of the late J. B. Francis, Past-President, Am. Soc. C. E., were contained between the limits of 0.736 to 1.006-ft. head on the weir; he should have added that only the experiments on weirs with end contractions suppressed were referred to, being included in the series numbered 44-55 and 67-71,

* Albany, N. Y.

† *Transactions*, Am. Soc. C. E., Vol. LXXX (1917), p. 951.

Mr. Nagler.

with a weir 9.992 ft. long. The writer did not attempt to make his work comparable with any experiments on contracted weirs. The mean depth of the channel behind this suppressed weir used by Mr. Francis was 5.048 ft. The pipes communicating with the hook-gauge chamber opened near the bottom of the channel, 6 ft. from the weir.* Mr. Stearns states that the writer's point of measurement for his Gauge 2 was not comparable with that used by Mr. Francis, although it was 6 ft. from the weir, because it was not about 4.80 ft. below the weir crest. However, since the writer's weir crest was only 3.72 ft. above the bottom of the channel of approach, he believed that he was fulfilling the conditions of the Francis weir by locating the point of measurement 6 ft. from the weir and near the bottom of the channel. Incidentally, Mr. Francis† found the difference in the head measured 6 ft. and 12 ft., respectively, from the weir to be "inconsiderable," and on an average equal to only 0.0014 ft. for heads on the weir very nearly equal to 1 ft.

The accuracy of the statement that Gauge 1 in the writer's experiments measured the head on the weir at a point comparable with that used by Messrs. Fteley and Stearns has also been questioned by Mr. Stearns. The point used by the writer was 6 ft. from the weir and 0.414 ft. below the weir crest, and, quoting from the paper by Messrs. Fteley and Stearns on "Description of Some Experiments on the Flow of Water Made During the Construction of Works for Conveying the Water of Sudbury River to Boston,"‡ we find that these experimenters used a point quite similar:

"The orifice in the glass was 0.04 ft. in diameter, and was originally 6 ft. from and 0.414 ft. below the level of the crest of the weir; it was afterwards moved 0.02 ft. higher."

This was the point used by Messrs. Fteley and Stearns in their experiments on velocity of approach, in which they varied the height of the weir above the bottom of the channel of approach; and although this point of measurement was not used in all their experiments, the writer adopted it as being representative, since it is also practically equivalent to the point of measurement used in their experiments on the 19-ft. weir.

In all the writer's gauges, the 2-in. pipe connecting with the hook-gauge wells entered the flume normal to the walls. The end of the pipe was carefully dressed with a file and was flush with the inside wall, in no case projected beyond the wood. The writer is of the opinion that when all other conditions are the same, the most accurate piezometer would be that which gives satisfactory results with a connection of maximum cross-section and opening with the body of

* "Lowell Hydraulic Experiments", p. 107, also Plate XIV, Figs. 9, 10, and 11.
† *Ibid*, p. 141.
‡ *Transactions*, Am. Soc. C. E., Vol. XII (1883), p. 9.

Mr. Nagler.

flowing water. Such a piezometer would respond most readily and accurately to fluctuations in the flowing stream, give a result covering a greater average of static conditions, and be less likely to respond to the influence of small stray diagonal currents. A piezometer with a 2-in. orifice and short 2-in. pipe connection with the stilling well, should produce more accurate results than small ¼-in. or ⅜-in. orifices with long rubber hose connections, similar to those used in the weir experiments of Messrs. Fteley and Stearns.

The writer still wishes to maintain his opinion that, in general, large scale weir experiments have been limited to those on low heads, due to the limitations in the size of the measuring basin. Operating under a head equal to the highest one on the writer's weir, the discharge over the Francis suppressed weir would have filled his basin in but 41 sec.; the Fteley and Stearns 19-ft. weir would have filled its enormous basin in but 9 min., and the standard Bazin weir would have filled its basin in less than 1½ min.

Almost all weir formulas are practically identical in their introduction of the more significant variables such as L and H. The main difference is usually defined in their method of introducing the "velocity of approach" correction and its magnitude. Hence, in testing the applicability and accuracy of the different formulas, it would seem that the logical procedure would be to magnify the necessity for the introduction of this factor of velocity of approach, instead of minimizing it; and the formula which is the most accurate when a large velocity of approach correction becomes necessary, is that which most correctly incorporates this element. The writer, therefore, wishes to take exception to Mr. Stearns' statement that his high head experiments seem to "have little general value, because of the high velocity of the water in the channel of approach", and, for the same reason, he suggests by the title of his paper that his experiments verify the Bazin formula. Mr. Stearns also presents a comparison of the effect of velocity of approach in the extreme case for the Bazin experiments as 0.144 ft. on a weir 0.80 ft. high, and for the Fteley and Stearns experiments as 0.128 ft. on a weir 0.50 ft. high, whereas the writer's maximum case was 0.377 ft. on a weir 3.72 ft. high. Without mention of the measured head on the weir, however, this comparison is worthless and would lead one to infer that the greatest effect was that which occurred in the hydro-chemical experiments. This, however, is not the case. Expressed as a percentage of the discharge over the weir, the effect due to the velocity head of approach in each case is as follows: Bazin experiment, 17%; Fteley and Stearns experiment as much as 25%; and the hydro-chemical experiment, 17 per cent. Actually, therefore, Messrs. Fteley and Stearns, themselves, have presented the Profession with the experiment involving the maximum effect of the velocity in the

channel of approach to the weir. It also appears that the writer's experiments are within the limit of those of Bazin on the effect of velocity of approach, and in verifying the Bazin formula for high heads there is fair assurance of the applicability of this formula to weirs of other heights discharging water under similar heads. Mr. Nagler.

Far more important than the production of a uniform velocity in the channel of approach seems to be the production of smooth stream-line motion in the water approaching the weir. A channel with a mathematically uniform distribution of velocities is not in equilibrium, due to the increased friction near the sides and bottom. A channel of approach of considerable length is not only advisable but necessary to produce the best condition. The conditions may be improved by the addition of screens or baffles; but, in many instances, screens alone, with a short channel of approach, would not produce the desired condition. Messrs. Fteley and Stearns performed experiments in which the channel of approach was so short that it was necessary to place the screens as close as 12 and 7 ft. from the weir; in the latter case, the screens were only 1 ft. from the point of measurement of the head. Bazin intimates that this unfavorable condition may possibly be the cause of the constant differences in the two Fteley and Stearns series of experiments and the discrepancy between their results and those of other experimenters. It is interesting in this connection to note that the production of eddies or a non-uniform distribution of velocities near the weir would tend to decrease the discharge over the weir; whereas, those experimenters using the shorter channels of approach, necessitating the use of screens, secured the smaller discharge, while those using the longer channels of approach, with screens far distant from the weir, or none at all, secured the higher coefficients of discharge.

When the writer mentioned waves of magnitude in the channel of approach for the experiments with the greatest discharge, he did not wish to convey an exaggerated impression of the unfavorable condition. In the worst case, the waves were only 1 or 2 in. high, and, being momentary, did not affect the constancy of the hook-gauge readings and, therefore, were not considered objectionable.

The distribution of velocities shown in Fig. 11 was the result of current-meter gaugings taken early in the progress of the hydro-chemical experiments. This condition was improved immediately by shifting the maximum velocity from the left to the center of the stream. The low velocity at the surface was attributed to the floating raft, and disappeared with approach to the weir. The object of the raft was to decrease the surface vibrations. As the ties only sank 3 or 4 in. in a channel from 4 to 8 ft. deep, the writer considered them negligible when the statement was made that the basin was free for 90 ft. above the weir. Fig. 11 shows more than 70% of the section

Mr. Nagler.

with a velocity greater than 3 ft. per sec. and not exceeding 3 ft. per sec. by more than 10 per cent. Comparatively, this is a far more uniform distribution of velocities than that observed in the Fteley and Stearns experiments on the 19-ft. weir, which Mr. Stearns once thought "quite satisfactory".* In fact, if one computes the velocities shown in Fig. 11 in the same manner in which Messrs. Fteley and Stearns presented the tabular results of their current-meter measurements in the channel of approach, one will find that the arithmetic mean of the individual departures from the average velocity in the section expressed as a percentage of the average velocity, is equivalent to 11% in the Fteley and Stearns channel of approach, whereas, the velocity distribution displayed in Fig. 11 gives a value of less than 5%, or more than twice as good a distribution as that once considered by Mr. Stearns as "quite satisfactory". Furthermore, the kinetic effect of the velocity of distribution shown in Fig. 11 is less than 3% smaller in effectiveness, in the production of "additional discharge due to velocity of approach", than that of a rigidly uniform distribution. A decrease of 3% in the velocity of approach correction is negligible, and represents the maximum effectiveness of screens or other devices which might have been added to the writer's flume in an effort to produce a still more uniform distribution of velocities. The effect of such screens would have been to produce a still greater discharge over the weir, instead of a smaller discharge, as Mr. Stearns seems to intimate.† For the reasons mentioned, there appears to be no foundation for Mr. Stearns' statement that, "judging from the high discharge over the author's weir with moderate heads, the conditions in his case were especially unfavorable". One is rather led to the opposite conclusion, namely, that conditions must have been especially favorable.

Fig. 25 involves velocity of approach rather than elimination of it, as Mr. Stearns would have one believe. The diagram may present a comparison of the different weir experiments with some degree of approximation, but its method of preparation is such that it does not present an infallibly true relation. In order to be absolutely correct, each individual experiment should have been treated with a velocity of approach correction differing from the others, in order to reduce the experiment to a channel of infinite depth. This correction is known only within certain limits and cannot be expressed by the mean value found by any experimenter, as these values $\left(\alpha \text{ in } h = \alpha \frac{v^2}{2g} \right)$ vary systematically for weirs of different heights and under different heads.

* *Transactions*, Am. Soc. C. E., Vol. XII (1883), p. 74.

† For a mathematical treatment of the effect of non-uniform distribution of velocities in the channel of approach, the reader is referred to *Water Supply Paper* No. 200, pp. 17 to 20.

Mr. Nagler.

Messrs. Fteley and Stearns found that α varied from 1.33 to 1.87,* and adopted $\alpha = 1.5$ only as a mean value. The application of such a mean value of α to all the individual experiments, in an attempt to eliminate the effects of velocity approach, rather involves this factor, and presents the experiments in neither a proper relation to themselves nor to those of others. Likewise, Bazin found that α varied from 2.52 to 1.08, and, in presenting a method comparable with that adopted by Messrs. Fteley and Stearns, suggested the use of $\alpha = \frac{5}{3}$, stating, at the same time, that this method of correction for velocity of approach was not satisfactory. Bazin arrives at the following conclusion:

1st.—That the values of α decrease with decrease of height of weir, and that, for a given height, they first increase with the head, up to a maximum, and then again decrease.

2d.—That the values of K (in the Bazin formula), which vary less than those of α with the height of the weir, become more nearly equal as the head increases.

Furthermore, in his series of experiments on a weir 0.75 m. high, Bazin found a mean value for α equal to 2.21, which would seem to indicate that the application of $\alpha = 1\frac{2}{3}$ to the hydro-chemical experiments on a weir 1.135 m. high, in the preparation of Fig. 25, would give results with a deficient magnitude of correction, even in the average case. There is no assurance that $\alpha = 1\frac{2}{3}$ is the proper correction for any or all of the hydro-chemical experiments shown on Fig. 25. Furthermore, there is evidence that $\alpha = 1\frac{2}{3}$ does not show the individual Bazin experiments in their true location on this diagram. The same statement might also be made of the other experiments shown thereon. As an illustration of the amount to which the selection of the proper value of α affects the location of the experiments in the production of such a diagram as Fig. 25, the writer has prepared Fig. 27, showing the location of the curve representing the hydro-chemical experiments reduced to a channel of infinite depth with α equal to different selected values. Fig. 27 shows an exceptionally wide variation in range and, particularly, for the higher heads, a possible variation much in excess of the difference between the results of the various experimenters. It suffices also to show that Fig. 25 does not eliminate the effect of velocity approach, although it may present an excellent attempt to do so.

A much closer approximation to a correct presentation of a comparison of the different weir experiments with those presented in the writer's paper, has been prepared in Fig. 28. In this diagram, the actual coefficients in $Q = C\,L\,H^{\frac{3}{2}}$, for the hydro-chemical experiments, have been shown for the experimental conditions of velocity of approach

* *Transactions*, Am. Soc. C. E., Vol. XII (1883), Table 1, p. 12.

Mr. Nagler.

under which they were performed. The application of an unknown value of α is thus eliminated. The results of other experimenters have been reduced to like channel conditions, not by attempting to correct their individual experiments, but by reducing their derived formulas. Fig. 28 is merely a graphical presentation of the tabulation expressed in Table 4. It is similar to Fig. 25, except that it gives results for a channel 3.72 ft. deep. It presents a true comparison of the results of other experimenters with the writer's actual experiments. An inspec-

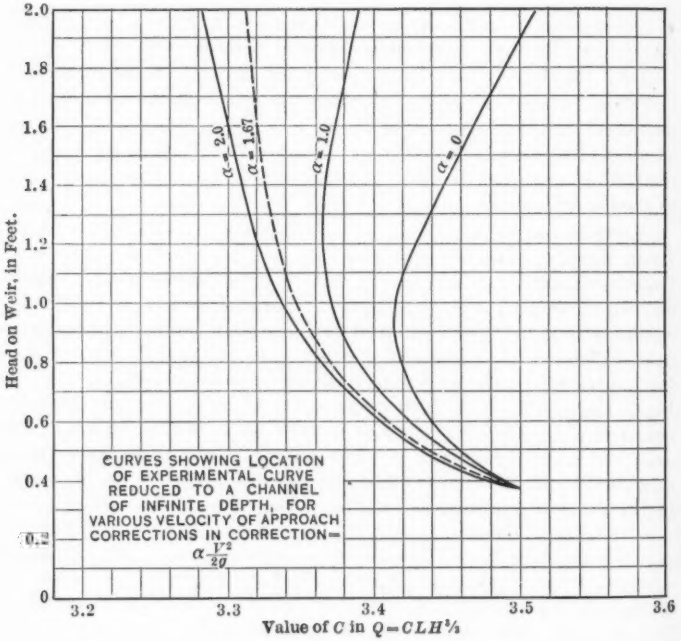

FIG. 27.

tion of Figs. 24 and 28 renders untenable Mr. Molitor's statement that in every case the Bazin experiments are smaller than those of the writer, and his conclusion that there is a constant or periodic error in the writer's experiments appears to be far from the truth. The hydro-chemical experiments do not give greater discharge than those of Bazin, except for the three experiments on the lowest heads, and even these fall within the limits of the Bazin experiments themselves. They verify the Bazin formula quite well for all heads, as well as the King formula and the Lyman diagrams for suppressed weirs, the latter two

Mr. Nagler.

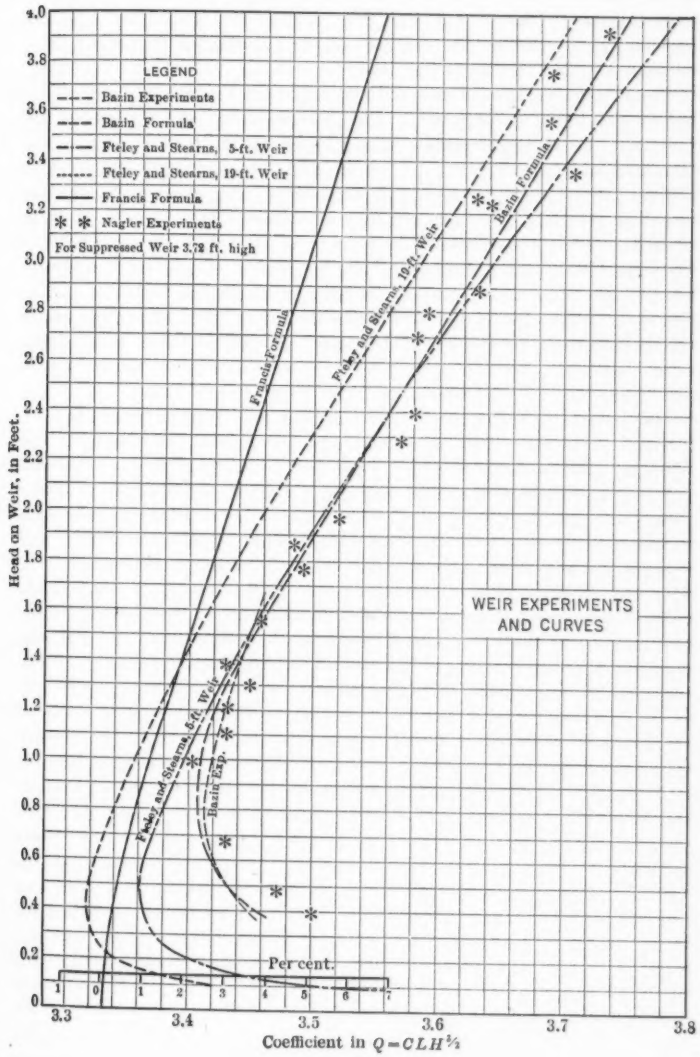

FIG. 28.

Mr. Nagler.

having been recently derived after careful study of all standard weir experiments to date. Likewise, the writer is pleased to note the excellent agreement in the formula proposed by Gustav Ritter von Wex, presented in Mr. Molitor's discussion.

Some writers have mentioned the fact that the Bazin formula did not fit the Bazin experiments. This statement apparently ignores the fact that the Bazin formula was not based on the experiments on the standard weir alone, but on a total of 371 experiments on weirs of different dimensions, an aggregate number equal to more than all other so-called standard weir experiments combined. His formula does fit the entire series to a remarkable degree. If Messrs. Fteley and Stearns had attempted such a generalization of results, considerable difficulty would have been experienced in reconciling their two series of experiments on weirs of only two different dimensions, and their final result which they based on the work of Francis, as well as their own, departs more widely from its few basic experiments than the Bazin formula does from the many experiments from which it is derived.

In general, a few experiments confined to a limited range in conditions, no matter what precision may be claimed for them, do not form as good a basis for the evolution of a formula as a greater number distributed through varying conditions and over a wider range in head, the precision of which may be somewhat inferior than in the former case. If the few experiments of Messrs. Fteley and Stearns on the 19-ft. weir so well determined the weir formula, the writer is curious to know why they finally chose a general weir formula which departs widely from these experiments, fitting more closely those of Francis and their own experiments on the 5-ft. weir. The Rehbock formula furnishes another illustration of this same principle. The experiments were made on so small a scale (the weir being only 1.64 ft. long, from 0.41 to 1.64 ft. high, and with heads on the weir of from 0.03 ft. to 0.59 ft.), that it seems ridiculous to attempt to classify this work with large-scale experiments like those of Bazin, Francis, and Fteley and Stearns. The representation of the Rehbock experiments by the formula on Fig. 25 is quite misleading, since there are no experiments above a 0.59-ft. head on the weir and extended down to a 0.03-ft. head. A true representation of his work would be shown by a curve starting with 0.59 ft. on the weir, following that shown on Fig. 25, and extending beyond it in a downward direction across the entire chart, intersecting the right-hand boundary ($C = 3.6$), at about 0.055-ft. head. Mr. Stearns is also in error when he states that the Rehbock experiments above 1 ft. on the weir show very little change in coefficient with increasing heads, since Rehbock performed no experiments above 0.59-ft. head on the weir to indicate such a proposition at all; and the extension of the Rehbock formula to these higher limits is entirely unwarranted.

Mr. Nagler.

In contrast to the refined work of Bazin, in passing a given quantity of water over weirs of different lengths with side contractions suppressed, thus forming the basis whereby his formula gives the variation in C, which is greater than that of other experimenters, as shown by Mr. Stearns, the Tremont turbine tests involving the side contraction of weirs should have but little weight. In fact, if Mr. Stearns had used the correction for side contractions evolved by Francis for this very set of experiments, he would have been forced to quite a different conclusion. Mr. Francis* performed these experiments with the intention of determining the effect of side contractions, and developed the formula for these Tremont turbine tests, namely, $L = (l - 0.05\ nh)$, where L equals the corrected length; n, the number of contractions; l, the actual measured length of the weir; and h, the observed head. The change in the coefficient of the second term of the binomial from 0.1 to 0.05 quite materially affects the results in Table 7; and since Mr. Francis himself finally adopted 0.1 for the value of the coefficient merely because of its simplicity, the writer recomputed Table 7 on the more correct basis. The results show the "average difference" in the case of the Fteley and Stearns formula to be + 1.13%, in the case of the Rehbock formula, + 1.03%, and the Bazin experimental curve, — 0.43%. In other words, the Fteley and Stearns and Rehbock formulas do not increase as rapidly with decreasing heads on the weir by more than twice the amount which the Bazin experimental curve is found to exceed the proper rate of increase as indicated by the Tremont turbine experiments. A correct computation of these experiments, therefore, shows far better agreement with the Bazin formula than with the other two.

Mr. Molitor calls attention to the Rafter experiments, with heads on the weir as great as 4.67 ft., noting that they do not agree with the hydro-chemical experiments. Fig. 29 has been prepared to show a graphical comparison of the Rafter experiments with those of the writer. This diagram is similar to Fig. 28, being based on a weir 3.72 ft. high. The coefficients for the Rafter experiments which were on a weir 5.2 ft. high, have been reduced to equivalent coefficients for a weir 3.72 ft. high, by correcting the observed head by an amount equal to the difference in velocity of approach correction on weirs 5.2 ft. and 3.72 ft. high, respectively. A mean value of $\alpha = 2.2$ was used, being that found by Bazin in his experiments on velocity of approach for the weir most nearly equal to 3.72 ft. This is probably as close as the true correction could be approximated, and involves but little error, due to the fact that the discharge over the weir in the Rafter experiments was computed by the Bazin formula itself. The diagram reveals several facts: First, that the Rafter experiments are quite inconsistent within themselves, departing as much as 2% from the best curve which could be drawn through the series, even in instances

* "Lowell Hydraulic Experiments," p. 86.

Mr. Nagler.

at the lower heads; second, that there are only five experiments above 2 ft. in head, in contrast to eleven hydro-chemical experiments above this head; and these five high head experiments represent discharge coefficients from 1 to 5% less than the writer's experiments, coming into closer agreement for the higher heads; and third, that Experiments Nos. 6 and 12 in the Rafter series give higher coefficients than the hydro-chemical experiments, and, hence, Mr. Molitor's statement is not strictly accurate.

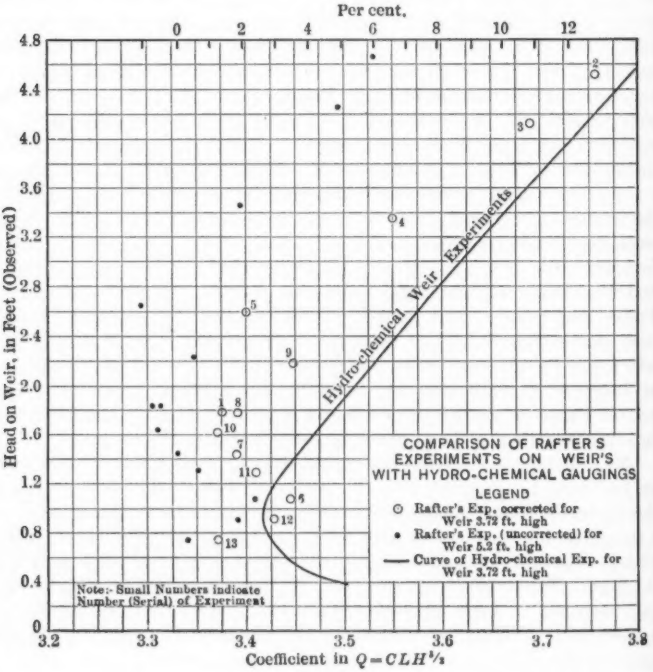

FIG. 29.

The Rafter experiments were in no sense volumetric experiments. A weir was used to gauge a weir of another length with different channel conditions; and it would hardly seem that they should be given much weight alongside of more accurate methods for determining the quantity of water passing over a weir. The discussion* of Mr. Rafter's work by Gardner S. Williams, M. Am. Soc. C. E., offers abundant proof as to the error in the Rafter experiments, error

* *Transactions*, Am. Soc. C. E., Vol. XXVI (1892), pp. 631 to 635.

sufficient, if allowed for, to make them come into close agreement with the hydro-chemical experiments. Mr. Nagler.

Mr. Molitor states that the hydro-chemical method of gauging has only high relative accuracy, and that its absolute accuracy must yet be proven. Can it be that the chemist has been mistaken and in processes of quantitative analysis has only been securing results of relative accuracy? The works of Collet, Stromeyer, and Mellet should afford some proof of the absolute accuracy of hydro-chemical gaugings. Mr. B. F. Groat has also presented some checks between hydro-chemical gaugings and volumetric and gravimetric gaugings, in which he found the two methods giving results agreeing within 0.2 and 0.3 per cent.* Mr. Molitor continues to mention sources of constant error which he fears may have existed in the writer's experiments. He mentions the effect of alkalis, acid, etc., in the pond water. The method of special dilutions in which laboratory solutions are made up in a series of trials, by mixing samples of the actual pond water and salt solution used in the test, absolutely eliminates all possibility of error from this source. Furthermore, if imperfect velocity distribution had affected the time that the salt reached the sampling station, its disastrous results would have become evident in a poor distribution of strength of samples. Table 2 shows not even moderate evidence of this, and also reveals that the whole mass of water as it passed the sampling section had practically the same concentration of salt. If differences had been observed in the samples, there might have been something more than speculation in Mr. Molitor's fears with regard to the location of sampling holes, peripheral flow, unequal distribution of velocities, and frictional losses in sampling pipes.

Water did not flow from the dosing station to the sampling point in imaginary stream lines, in which case the portions or elements retarded by friction would have arrived later; but there was interchange, many times, between the top and bottom and side elements, due to cross-currents and turbulence. This mixing was especially encouraged by the construction of baffles and a submerged weir in the flume between the two stations. The salt detection points in the water moving with low velocity, near the sides of the flume, proved that the salt solution traveled from the point of dosing to the sampling station, not with a velocity represented by the slow movement of the current in which the points lay, but equal to, and in some instances greater than, the mean velocity of the water in the flume. Finally, Mr. Molitor's last objection that there might be loss of salt by absorption in the flume walls, seems to be merely "straining at a gnat," when one considers that the flume walls are already soaked and filled with water to their capacity, and that, at best, the quantity of water absorbed in the walls represents only a small fraction of a percentage of the total volume of water discharged over the weir in any experiment.

Paper No. 1428

DETERMINATION OF THE DUTY OF WATER BY ANALYTICAL EXPERIMENT*

By W. C. Hammatt, M. Am. Soc. C. E.

With Discussion by Messrs. J. C. Van Reigersberg Versluys, W. L. Rockwell, J. C. Stevens, S. T. Harding, and W. C. Hammatt.

Synopsis.

The purpose of this paper is to show the methods used in the determination of the quantity of water required for the growth of certain crops, where it was impracticable to measure it directly. This was done by analyses of the requirements and by the separate determination, by experiment, of the specific quantity required for the different parts which go to make up the whole use of water by the plant. The circumstances attending the investigation described herein were such as to open up a new field which is not covered to any great extent in available technical literature. The writer hopes that the description of his work in this case will bring forth discussion from others who may have treated this matter along similar or different lines, as this may broaden the scope of the literature on this very important subject.

The term "duty of water" has no hard and fast definition, and is considered by various investigators as representing different things. Some consider it to be the average annual quantity, in acre-feet, applied

* Presented at the meeting of March 20th, 1918.

by the farmers in a particular locality, or on a certain class of soil, to produce their crops. Others consider it as the minimum quantity which, if applied under certain conditions, will produce a crop. The writer considers it in these pages as the quantity which can be applied with the greatest efficiency, under given conditions, for the production of crops.

Many researches have been made in various States and agricultural localities by the Office of Experiment Stations or by State agricultural colleges, professing to obtain the duty of water for the particular localities and under the particular conditions obtaining in the area covered by the investigations. Among the most complete of these are those of Don H. Bark,* and the United States Department of Agriculture.† These investigations attempted to fix the economical duty by dividing each tract into three parcels, applying different quantities of water to each, and observing the results. This was a step ahead of any work done heretofore, but did not produce results sufficiently comprehensive, due to the great differences in the quantity of water applied and to the lack of a complete analysis of the reasons for the results obtained.

The experiments to be described later were for the purpose of determining the duty of water for the propagation of certain wild grasses in Southeastern Oregon. They were confined to two localities, the valley of the Chewaucan River, in Lake County, and the valley of the Silvies River, in Harney County. In both localities, crops of wild or native grasses are raised for forage purposes, the raising of beef cattle being the main industry. Climatic conditions in these two regions are such that crops of greater value cannot be raised economically. Both regions are subject to long and severe winters, and, even in the summers, killing frosts frequently occur, no month of the year being free therefrom. Although some garden truck is raised for local use, and there are occasional patches of alfalfa and grain, the raising of any of these on a commercial basis is a hazardous undertaking. The raising of native wild grasses, however, inured to the existing climatic conditions, is very profitable, such grasses having good food value, and the cattle raised thereon being famous for their quality.

† Reports for 1910, 1911, 1912, and 1913.

In the Chewaucan River Valley, Fig. 1, the river, on emerging from the mountains, flows on to a broad marsh, almost level transversely, and with a uniform fall longitudinally of about 1 ft. per mile. This marsh is divided into two parts by spurs of the mountain extending toward its center, leaving only a narrow channel between their extremities, through which the water passes from the upper to the lower end. This gives the marsh an hour-glass form, the area of the upper end being about twice as great as that of the lower, and

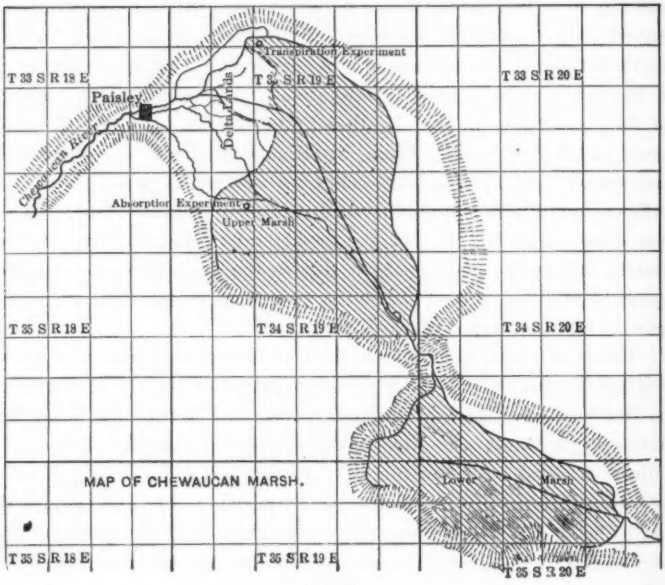

FIG. 1.

the two parts being designated the Upper and Lower Marshes, respectively. In former years, the spring freshets emerging from the mountains and discharging on the upper end of the upper marsh, spread indiscriminately over it, inundating it for long periods; the waters were gathered together again at the Narrows and at the lower end of this canyon, being again spread on the lower marsh, which they inundated before being again gathered together and discharged into Lake Abert, about 4 miles below. These inundations caused the growth of many plants of a somewhat aquatic nature, some of which were valuable for the

feed of animals and some of which were not. During the winter, this growth died down and was trampled by such stock as went on the marsh, so that a peat soil, from 1 ft. to several feet in thickness, has been built up. The nature of the inundations was such that full value could not be derived from the marsh for feeding purposes, on account of the likelihood of stock being trapped by freshets and lost by miring. The owner at that time, therefore, began to establish works for the purpose of controlling the water on the marsh and for facilitating drainage after the freshets ceased. These works have been amplified by successors in ownership, so that now there is quite a comprehensive system of works, designed to facilitate the even distribution of irrigation water and hold the freshet water off the marsh during such seasons as it would work injury rather than be beneficial for irrigation. The nature of the plants is such, due to the fact that they had their start under conditions of continuous flooding, that the same general method of applying water is still carried out. As will be described herein, however, the control of the water has caused an improvement in the nature of the plant growth, and will ultimately cause all the valueless plants to be replaced by those having a value for stock feed.

In the valley of the Silvies River (known as Harney Valley), Fig. 2, the river emerges from the mountains and splits up into various sloughs and branches, forming a delta over which the water has spread during times of freshet and annually causing the growth of certain wild grasses. Unlike the Chewaucan River, however, this is not a peat marsh, and the waters are not again brought together into one channel, but, after flowing over an area of considerable extent, are discharged into Malheur Lake. On account of the topography, the runoff is much more rapid, and the irrigation, consequently, is of shorter duration, so that the nature of the soil and of the crops is far different from those on the Chewaucan Marshes. To be sure, there are some pockets of small extent where conditions have been such as to cause the formation of peat layers and the growth of grasses similar to those on the Chewaucan Marshes, but, in the main, the growth is of a different nature.

Alkali.—In both the localities described, the valleys are surrounded by a volcanic formation locally known as the Rim Rock. The disintegration of the volcanic rocks releases alkaline salts, in greater or less

quantities, so that, though the water itself carries a very low proportion of such salts, the soils—of considerable porosity and capillarity—have accumulated them to a large extent by absorbing their quota of the flood water and later giving up the free water therefrom by soil evaporation. This characteristic of the soil limits and determines the nature of the plant growth which can thrive thereon, and also prevents any form of irrigation which does not provide for carrying away the alkaline salts which otherwise accumulate on the surface.

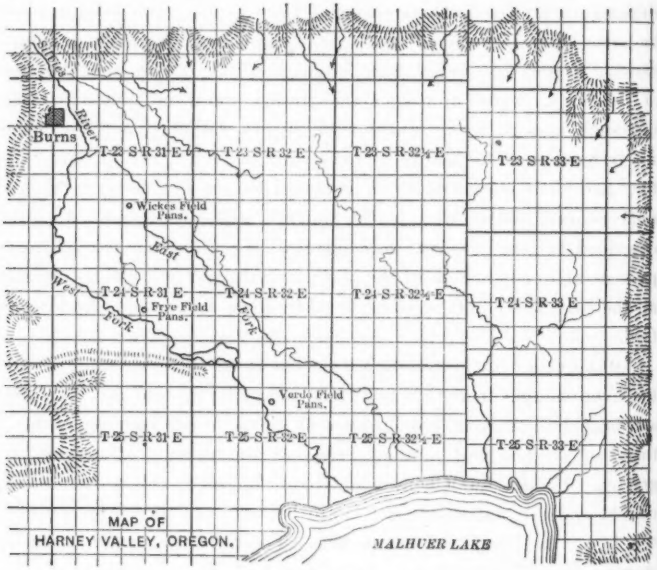

FIG. 2.

Chewaucan Marsh is underlain beneath the peat with a chalky substance which absorbs water with great readiness, but resists its passage to a large extent. The nature of the subsoil is such that it is continually saturated, but permits of little or no loss by deep percolation. Even in continuous droughts, the ground does not dry to a great depth, as the subsoil gives up its water reluctantly.

The soil on the uplands at the head of the Chewaucan Marshes, which uplands are really a fan-shaped delta over which the waters of the river originally spread before flowing to the marsh, is of a different

nature. This soil is a fine, sandy loam, becoming more sandy with depth until the subsoil—of the same nature as that under the marsh—is encountered. In its general characteristics, the soil of the uplands above the Chewaucan Marsh is similar to that of Harney Valley.

Climate.—As already stated, the climate of Southeastern Oregon is very severe; winter lasts from October to March, the temperature often reaching many degrees below zero. The growing season is short, lasting only from April to September, and killing frosts are frequent in every month of the year. Two stations of the U. S. Weather Bureau are in the vicinity of Chewaucan Marsh, one at Paisley, 2½ miles above the marsh, and the other at Valley Falls, about 4 miles below it. The Weather Bureau station at Burns, Ore., at the head of the Harney Valley, provides data in regard to climatological conditions in that valley. For the purpose of indicating the nature of the climate in this vicinity, Tables 1 to 4 show the maximum, minimum, and mean temperatures for the stations at Paisley and Burns for a period of 11 years. Tables 5 and 6 show the maximum, minimum, and mean precipitation at the same stations for the same period of years.

Annual mean = 47.4.

Nature of Experiments.—As it was impracticable to segregate certain measured areas and determine their actual use of water, some other method had to be devised. After a careful study of conditions, the writer decided that the analytic method was probably the best, and would also lead to obtaining data which would be valuable in the determination of any changes of system which it might be desirable to make later for the purpose of improving irrigation conditions.

The analytic method consisted in dividing the water into its various uses and making a separate determination, as far as possible, of each use. In this manner, any of the determinations which were based on estimates, or for which the data were inadequate or unreliable, would affect only the particular item concerned, and not the whole duty of water. Another advantage of this method of determination is that, by a study of the different factors making up the analysis, unnecessary or reparable losses may be discovered and the system improved so as to eliminate them.

In a strict sense, the only water actually used by a plant in its growth is that taken in through the roots and either remaining as a component part of it or being given off through its leaves by the process of transpiration. However, as it is impossible to deliver water to the roots directly, and as, even if it were possible to do so, it would be necessary to pass the water through the soil in order that it might take into solution the salts necessary for plant growth, there are various other uses which can be considered as beneficial to plant growth. Consequently, it may be considered that the various components into which the beneficial use of water is divided are as follows:

(1) Soil Moisture,
(2) Soil Evaporation,
(3) Plant Use,
(4) Soil Losses.

Mean annual precipitation = 12.01.

(*1*).—*Soil Moisture.*—The necessary soil moisture differs in different cases. Some plants require a soil having little more than hygroscopic moisture; from this minimum the requirements of various plants increase through all gradations, some even requiring a saturated soil with free surface water. Among the latter, the most widely known is rice.

(*2*).—*Soil Evaporation.*—As water cannot be brought through the soil to the roots of plants without a certain proportion being drawn to the surface by capillarity and thence evaporated, soil evaporation may be considered as a beneficial use. This evaporation will vary

according to the method of irrigation and the nature of the plant—deep-rooted plants irrigated by sub-surface application requiring very little soil evaporation, and those which must have a saturated soil and free surface water requiring a very high evaporation.

(*3*).—*Plant Use.*—Plant use consists of the water going into the plant structure and that given off by transpiration through the leaves. The first is negligible when compared with the other components. Transpiration, however, is one of the most important uses of water.

(*4*).—*Soil Losses.*—Certain losses in the application of water are necessary, for various reasons: Few subsoils permit of the application of water by any of the irrigation methods in general use without deep percolation or subsoil losses. The nearer to saturation the soil is required to be, the greater will be the underground losses. Where free water is required on the surface, a certain quantity of this must be drained off, in order that continuous evaporation will not cause the concentration of the injurious salts carried. In some cases, a movement of water is also required in order to avoid the loss of air from the water and the consequent stagnation which is injurious to such plants. This movement necessarily entails an additional loss, that of run-off.

To the foregoing may also be added delivery losses in bringing the water to the land. In this paper, however, these losses are not considered, as the duty of water is here treated as the net duty on the land, and not the gross duty from the point of supply.

The growth on the Chewaucan Marshes consists of certain grasses of local importance which are little known in other parts of the country. The most valuable of these are the "Awned Sedge" (*Carex Aristeta*) and "Sprangle Top" (*Scholochloa Festucacea*). There is very little literature on these two grasses, and their habitat seems to be extremely limited. Both occur only in severe climates, no examples being known south of the forty-second parallel of latitude, and they are found on the North American Continent only in Canada and some of the most northerly parts of the United States. They grow in profusion in a few places in Oregon, and all that have been examined seem to require a peat soil and conditions of inundation during the growing season. Apparently, a distinct movement of the water is also necessary, as any check in the flow seems to cause a replacement of these grasses by tules, cat-tails, and other waste growths which thrive

in still or stagnant water. Where conditions are right, in regard to the period of inundation and the flow of water, and where the soil is a true peat, the plants attain a height of from 4 to 8 ft., cutting from 2½ to 5 tons of cured hay to the acre. Where water is plentiful, and the inundation is continuous during the growing season, neither of these grasses flowers, but the growth goes entirely to stalk and leaf. In this condition, the appearance of both kinds is very similar, so that only a person familiar with the characteristics of the two plants is able to distinguish one from the other. They are locally known as "Sugar Grass", the term being applied indiscriminately to the two varieties. The two occur sometimes in mixed patches, and sometimes in patches containing only one of the varieties.

Where the water supply fails before the culmination of the growth of these plants, and where such plants reach maturity under conditions of a moist soil, instead of a saturated soil with surface water running over it, they sometimes go to seed, particularly the Sprangle Top. This condition obtains on various high knolls which do not receive as much water as the remainder of the marsh, and the appearance of the plant in flower is so different from that before flowering that it has been popularly supposed to be of a different variety, and is locally known as "Rice Grass".

There have been no exact experiments to determine the food value of the plant, either by feeding to stock or by analysis of the hay. Among the ranchers conversant with this subject, however, it is generally conceded that, pound for pound, Sugar Grass hay is equal to Alfalfa for the fattening of beef cattle. There is a difference of opinion as to its value for feeding work stock, some holding that work horses hold up slightly better on Timothy hay, and some claiming that Sugar Grass hay is equal or superior to Timothy hay for work stock as well as beef cattle. The fact remains, however, that the company operating the marshes feeds more than 10 000 head of cattle for 5 winter months on 20 lb. of Sugar Grass hay per day per animal, bringing them out in the spring in much better condition than they were when they went in in the fall, and also that, during the harvest season, both the cow-ponies and the draft animals on the harvesting machinery are worked under extremely severe conditions on a diet consisting only of Sugar Grass hay, without a pound of grain, which shows that the food value is excellent.

FIG. 3.—NORMAL GROWTH OF SUGAR GRASS.

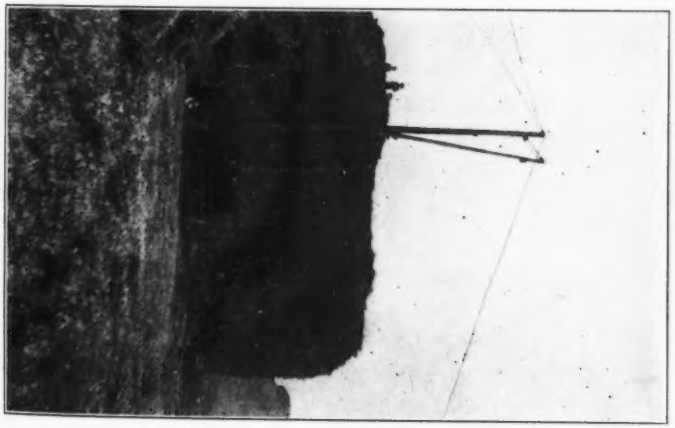

FIG. 4.—STACKING SUGAR GRASS HAY.

FIG. 5.—FIELD OF SUGAR GRASS DURING CUTTING.

FIG. 6.—TRANSPIRATION EXPERIMENT BY CUTTING.

The vegetation in Harney Valley consists of a miscellaneous growth of wild or partly wild grasses. A large part of the land was seeded in the past to Timothy and Red-top, and traces of these grasses remain throughout much of the valley. Mixed with them, however, on the sedimentary soils, are found "Nevada Blue Grass", "Soft Leaf

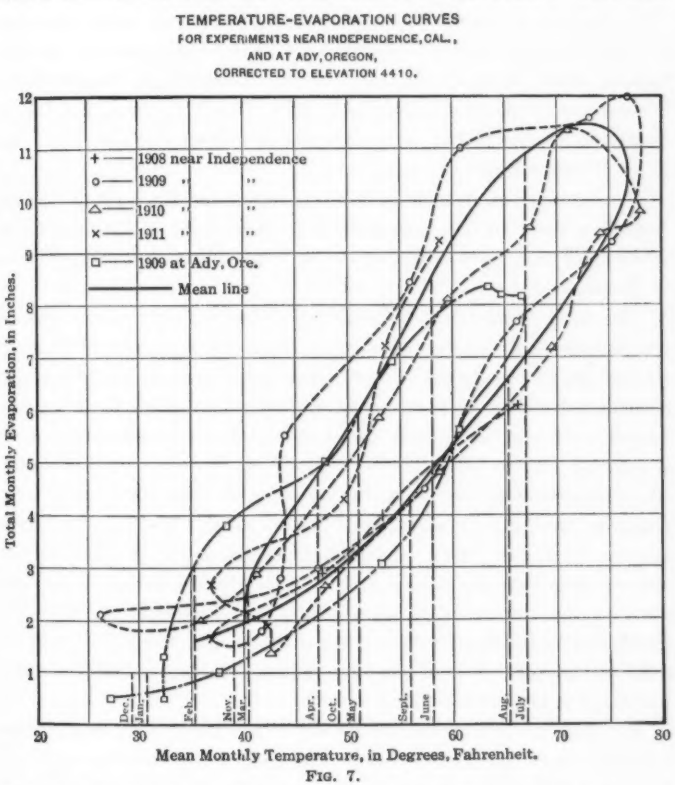

FIG. 7.

Sedge" and other less valuable wild grasses. Where peat soil occurs, heavy growths of "Sugar Grass" are found.

Evaporation.—Very few evaporation measurements have been taken in Oregon, and the conditions attending these investigations have been such as to make it impossible to carry on continuous experiments through all parts of the year. Continuous evaporation experi-

ments, however, have been made in various places in California, and those in Owens Valley by C. H. Lee, M. Am. Soc. C. E., during the period from 1908 to 1911, under the auspices of the Los Angeles Aqueduct Commission and the U. S. Geological Survey,* were taken as most nearly conforming to conditions as they occur in Eastern Oregon. The elevation of Owens Valley above sea level at the point where the Lee experiments were undertaken is 3 775 ft.; the elevation of Chewaucan Marsh is approximately 4 410 ft. Temperature conditions for Chewaucan Marsh are shown by Tables 1 and 2; those for Owens Valley were obtained in a similar manner from the records of the U. S. Weather Bureau.

The method of deducing the evaporation for the various months from free water surface near Paisley is shown by Fig. 7. In order to understand this matter thoroughly, a few preliminary points should be discussed.

The measurements of evaporation in Owens Valley were corrected for altitude in the inverse proportion which the barometric heights in the two places bore to each other. Although it has never been proved, academically, that evaporation at different elevations is in inverse proportion to the barometric pressure, the writer's observations have always led him to believe this to be a fact. Relative to this matter, it is interesting to note that, in the paper entitled "A Study of the Depth of Annual Evaporation from Lake Conchos, Mexico",† by Edwin Duryea, M. Am. Soc. C. E., and H. L. Haehl, Assoc. M. Am. Soc. C. E.,‡ about a year after the experiments described in this paper, the authors tabulate the results of all evaporation measurements throughout a broad area in the Southwestern United States and Northern Mexico in order to show the effect of elevation, and this tabulation shows indubitably that it is as above stated.

For a barometric height of 30 in. at sea level, that at Elevation 3 775 would be 26 in., and that at Elevation 4 410 would be 25.35 in., from which it is seen that the evaporation at Elevation 4 410, all other conditions being equal, would be 16% greater than that at Elevation 3 775.

Professor Frank H. Bigelow and others have done considerable investigatory work to determine the relation between the evaporation

* Published in *Water Supply Paper No. 294.*

† *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 1829.

‡ Now M. Am. Soc. C. E.

from pans of various diameters and from lake surfaces. In the writer's experiments no consideration has been given to the possible lesser evaporation from a lake surface than from the pans used by Mr. Lee, due to the fact that conditions of cover were such as to make the evaporation more nearly conform to that found in pans than to that of a broad, uninterrupted lake surface.

In comparing the evaporation in Owens Valley with that in the places covered by this investigation, allowance must be made for differences in humidity. Although no data are obtainable as to the relative humidity in the two locations, observation on the ground and a study of the topographical conditions enables one to make an approximate allowance. The Chewaucan Marsh is enclosed by high bluffs which protect it, more or less, from the action of the wind, and cause the humidity during times of flood to be higher than in broad valleys like those of the Owens and Silvies Rivers, the latter two being somewhat similar in configuration, and humidity conditions being more nearly the same. Moreover, the growing season in the Owens River Valley is longer than in Oregon, but the proportion of flooded land is very much smaller, which would tend to make the humidity, during the early months of the year and also during the summer, higher in the Owens Valley than in the Oregon valleys.

On Fig. 7 is platted a curve in which the abscissas represent the mean monthly temperatures, in degrees, Fahrenheit, and the ordinates the total monthly evaporation, in inches, for each month from September, 1908, to May, 1911, corrected for difference in elevation between 3 775 and 4 410 ft. From this, a mean curve is constructed, shown by the full line. In Table 9 are given, first, the results of applying the mean monthly temperatures near Paisley to this curve and getting the corresponding evaporation by intersection with the mean curve; second, the assumed mean monthly evaporation near Paisley after making corrections for the difference in local conditions; and third, the monthly evaporations obtained by intersecting the curve deduced from evaporation measurements at Ady, Ore., by the mean monthly temperatures for the station near Paisley. The latter evaporation measurements were taken under the direction of the U. S. Weather Bureau, in 1909, at Ady, Ore., near Klamath Lake, at an elevation of 4 090 ft., and the curve platted on Fig. 7 is deduced from these measurements, correcting for the difference of elevation by increasing the

evaporation measurements 7½ per cent. These measurements were not available at the time the original computations were made, but, on making use of them, at present, it is interesting to note how closely they conform to the evaporation assumed, and how well the variations from the assumed ones are accounted for by the equalizing influence of Klamath Lake.

Having obtained the evaporation from the water surface by use of the diagram, Fig. 7, it was necessary to reduce this to the condition of evaporation from a thin sheet of water passing over the soil and to conditions of protection by plant growth.

The first correction was made by adding 33% to the evaporations obtained, as described for the water surface, as investigators have found that the evaporation from a thin sheet of water is greater than that from an ordinary water surface, varying between 25 and 37 per cent. As for the plant protection, conditions are such, due to the close growth of the plants, that the humid air is held impounded by their leaves without being swept away by the wind and replaced by dry air, thus making the evaporation lower than it would be for an unprotected water surface. In these experiments, therefore, it was assumed that the evaporation from a field containing fully developed plants would be only one-third of that from the same field without vegetation. The ratio of evaporation, therefore, was assumed to drop uniformly from its full quantity at the beginning of the growing sea-

son to one-third of that quantity at the end of that season, and the evaporation above determined was corrected in this manner. Therefore, the evaporation is corrected to conditions of plant cover, as follows:

March 15th to 31st	1.33 in.
April	3.11 "
May	2.96 "
June	3.11 "
Total	10.51 in.

In the Harney Valley analysis, time was available for more complete experimental work than was done on the Chewaucan Marshes. Pan experiments were made in order to determine evaporation in connection with transpiration, and, as the records of soil evaporation were thus directly determinable, no analysis was made for this valley by comparison with distant data.

The pans used for evaporation tests were 11.3 in. in diameter, and 4 ft. deep, having a surface area of 100 sq. in., and a soil depth of 3 ft. inside the pan. The pans were sunk in the soil to a depth of 3 ft., and the soil was replaced inside them in the same order as it was taken out of the pit, all vegetation, however, being removed from the surface in order that the record of the pan would give the soil evaporation without being affected by transpiration. The diameter of the pan appears to be a trifle small, but it was constructed in that way in order that its surface would receive, as nearly as possible, the same protection as the surrounding soil. A gauging well of small diameter was put in the pan in order that the depth to ground-water could be determined at intervals. Observations were made every few days, and enough water was added to bring the ground-water elevation to the same height as that in the natural soil outside the pan, the water being measured into the pan to replace evaporation losses.

At the end of the test, at harvest time, enough water was added to bring the ground-water level to the same height as that at the beginning of the test, the total water added thus equalling the evaporation during the period of the tests. The results are shown graphically on Figs. 15 to 20.

Transpiration.—One of the most important processes by which plants achieve their growth is that known as transpiration. The

structure of the leaves is such that their surfaces are covered with small openings or spores known as "stomata." Both surfaces are covered with these stomata, but the under surface has three or four times as many as the upper. Through these stomata the carbon from the air is admitted to the plant, and by a process in which sunlight forms an important part, this carbon, in combination with the water, is converted into starch, which forms a large part of the structure of many plants, particularly forage plants. The water taken in through the roots and flowing upward through the veins of the plant is evaporated from the surface of the leaves, serving to keep them moist and to operate the stomata, causing them to open or close and to regulate the quantity of air admitted, according to the requirements of the plant. This process has been described in various botanical and irrigation works,* and need not be mentioned herein. The quantity of water given off, however, is proportional to the quantity of starch produced by the plant and, consequently, to the growth of the plant itself, and the ratio of the quantity of water transpired to the quantity of plant matter produced, though not absolutely constant for certain plants, is within such close limits as to be to a certain extent measurable.

The quantity of transpiration, or the transpiration ratio, has been considered of such importance by scientists that many experiments have been made to determine it for many of the most common crops, particularly grains. Much valuable matter was contributed in this regard by the experiments of the University of Minnesota, prior to 1909, published by A. W. Sampson and L. M. Allen.† These studies showed the great effect of light on the quantity of transpiration, the lesser effect of heat, and the practically negligible effect of humidity. Fig. 8, reproduced from the "Minnesota Botanical Studies", shows the relations between the different phenomena mentioned.

Many other experiments have been made with soil pans in which plants are raised, the transpiration being measured by weighing the pan from time to time with its contents and weighing also the water applied, thus computing the water lost by transpiration. Descriptions of these experiments have been given in many scientific works and

* Such as King's "Irrigation and Drainage."

† "Minnesota Botanical Studies", Part 1, Vol. 4.

textbooks.* The determination in this manner, however, requires rather an elaborate experiment station and the constant attention of the observer.

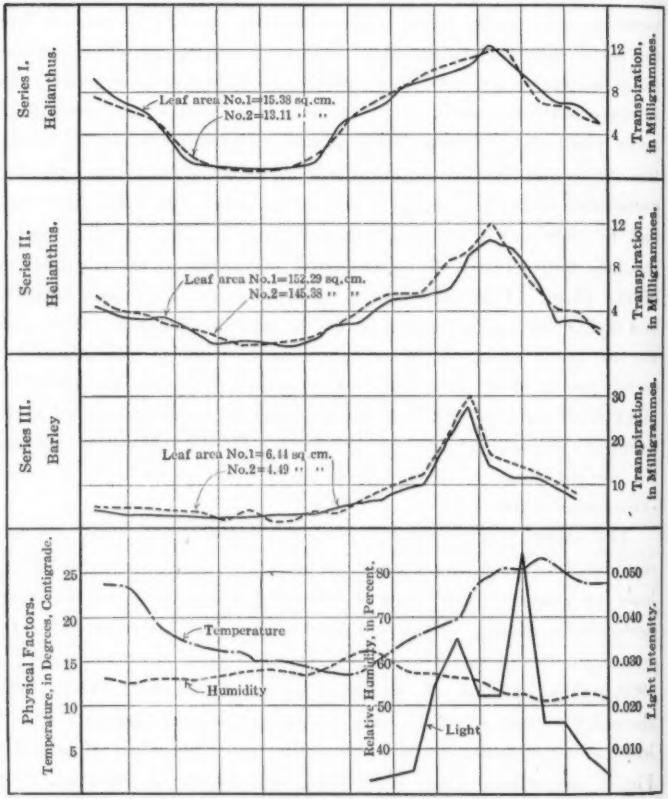

FIG. 8.

The transpiration ratio, or the relation of the quantity of water lost by transpiration to the quantity of dry matter produced for various crops, is shown in Table 10, taken from the work of Professor Fortier.

* Among these are "Irrigation and Drainage", by F. H. King; "Use of Water in Irrigation", by Samuel Fortier, M. Am. Soc. C. E.; and "Principles of Irrigation Practice", by John A. Widtsoe.

In describing experimental work done and deductions therefrom in connection with the water supply for Los Angeles, Cal.*, Mr. Charles H. Lee advances the theory that, if plants are cut, the water supply from their roots thus being instantly stopped, the transpiration will

* *Water Supply Paper No. 294*, U. S. Geological Survey.

continue from the stored water in the plants for a brief period at the same ratio as before they were cut. Acting on this theory, Mr. Lee made some experiments with alfalfa, using 15 min. as the period for which transpiration would remain constant.

In connection with the determination of the duty of water described herein, the writer made some experiments on the Chewaucan Marsh in order to determine the transpiration from sugar grass, following Mr. Lee's theory, and, though in doubt as to the maximum period for which transpiration will continue to be constant, he used 15 min. as the time, the same as Mr. Lee. It is interesting to note that, in experiments by pan methods, described later, the results are not

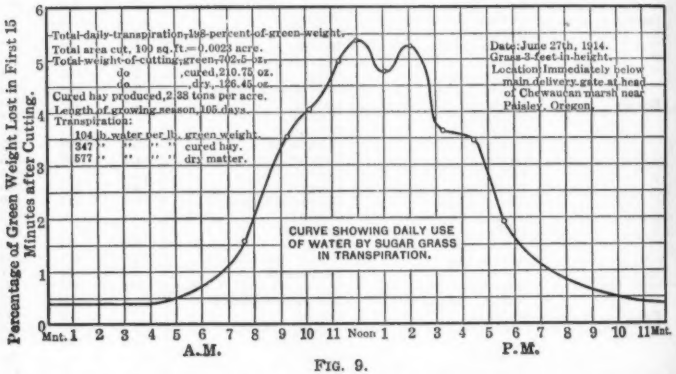

FIG. 9.

incongruous as compared with the more accurate experiments made subsequently. Fig. 9 shows graphically the loss at various hours of the day, from the growing plants, in percentage of the green weight of the cut plants.

This experiment was performed by taking a typical growth of sugar grass of considerable extent, where the distribution of the plants was uniform, and laying this plat off in squares containing 10 sq. ft., each. From each of these squares the sugar grass was cut, and was weighed immediately on cutting and 15 min. later, the loss in weight for this time being computed as a proportion of the green weight at the time of cutting. Immediately after the first weighing, the plants were spread on a canvas and made to cover the same area as while standing; they were left in this position until the time of the second weighing. Fig. 6 shows the apparatus used for this

purpose, which consisted of a scale, weighing accurately to half ounces, up to a maximum of 4 lb.

The result of this experiment showed the total transpiration for the day as 198% of the green weight of the plant at that period of its growth. As the plant was then full grown, it was considered that the green weight would vary uniformly from the time that it sprouted to the time when it had attained its full growth, which would be from about March 15th to June 30th, or about 105 days. This would make the total transpiration during the growth of the plant 104 times its green weight at the time of cutting, or 104 lb. per pound of green weight at the time of cutting. Fig. 10 shows the loss of weight of the green cutting in curing for hay. It was found that after 3 days in ordinary weather the curing was complete, and the loss was approximately 70% of the green weight at the time of cutting.

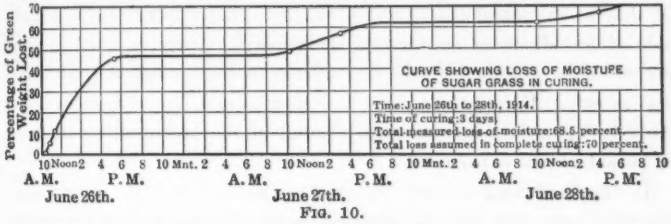

FIG. 10.

This would make the quantity of water transpired per pound of cured hay, 347 lb. It was also found that the cured hay contained about 40% of water; consequently, the transpiration per pound of dry matter would be 577 lb. This, however, is merely given for purposes of comparison with tables of transpiration for other plants which are reduced to a basis of dry matter produced, because, for the purpose of the experiments, the comparison was required with cured hay. Experiments were also made to ascertain whether or not the loss of weight was uniform for the first 15 min., and consequently equal to the transpiration rate. Although the experiments seemed to show that the rate of loss immediately after cutting was from 40 to 50% greater than after a period of 15 min., the chance of error in such small periods of time was considered great enough to warrant the experimenters in ignoring this result.

In the determination of the duty of water in Harney Valley, the experiments were more elaborate. As stated previously, the growth in

Harney Valley consists of various kinds of plants, and, consequently, experiments were conducted to show the transpiration for several kinds of growth, as follows:

Each experiment required an equipment consisting of three soil pans. Two of these were 35.7 in. in diameter and 4 ft. in depth, sunk 3 ft. into the soil, and having the excavated soil replaced in the pan in the same order as it was taken out, so that the top of the soil in the pan consisted of an unbroken sod containing the same growth as the remainder of the field. The third pan was 11.3 in. in diameter, 4 ft. in depth, sunk to the same depth as the other pans, and having the soil replaced therein in the same order, with the exception that all vegetation and plant growth were carefully removed, so that the pan would serve for soil evaporation only. As will be noted, the surface area of the two large pans was 1 000 sq. in. each, and that of the small pan was 100 sq. in. The evaporation pan was made of less diameter in order to maintain as nearly as possible the same conditions of shaded area as occurred in those pans covered with plant growth. Rain gauges were also maintained in connection with each set of pans, in order to take account of the precipitation during the period of the experiment.

At the beginning of the irrigation season, sufficient water was measured into each pan to bring the ground-water level therein to the same elevation as that in the soil of the field itself. Thereafter, observations were made at periods of from 4 to 10 days, and sufficient water was measured into each pan at each observation to keep the level at the same elevation as in the remainder of the field. A record was kept of the quantity of water introduced into each pan, the elevation of ground-water referred to the bottom of the pan, and such other data in regard to the growth of plants, the rainfall, and other conditions, as would aid in analyzing the results. At harvest time, sufficient water was introduced to bring the ground-water to the same elevation as that at the beginning of the test, the total water added thus equalling that used by the plants in transpiration plus the soil evaporation. In the final analysis of the duty of water, these two items were not segregated, but the total used in each pan was charged against transpiration and evaporation. For purposes of comparison with other transpiration data, however, the evaporation pan was used as a control, and the evaporation from

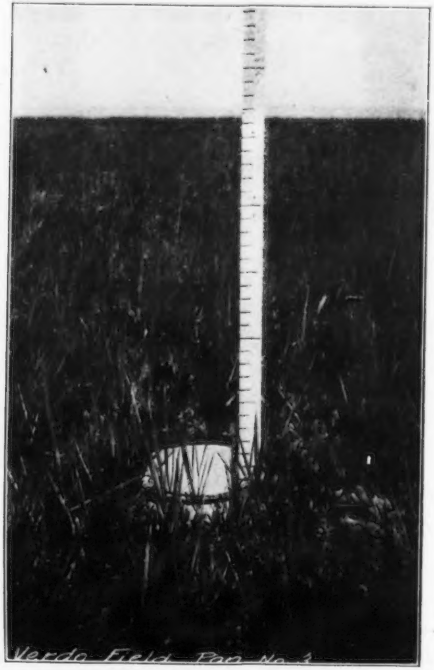

FIG. 11.—SOIL EVAPORATION PAN.

FIG. 13.—ONE OF THE TRANSPIRATION PANS AFTER HARVESTING THE CROP.

FIG. 14.—SINKING TUBE THROUGH SOD BY TURNING.

it was deducted from the total in the other pans, in inches of height, the difference being considered as transpiration. It is not claimed that this will give absolutely accurate results as to transpiration, for the reason that conditions in the evaporation pan, on account of absence of mulch due to growing sod, will be somewhat different from those in the transpiration pans, but, as the area of the evaporation pan was made small enough so that the adjacent growth would protect the surface practically to the same extent as in the large pans, the results would be sufficiently close to give an approximation to the transpiration. Whatever inaccuracies might occur in the calculation of either evaporation or transpiration were eliminated by the use of the results from this pan as a combined figure for evapo-transpiration.

Figs. 15 to 20 show graphically the mass curve of the quantity of water added to each pan, exclusive of that added at first to bring ground-water to the starting elevation, and the fluctuation of ground-water in the pan during the period of the test. The tests covered the irrigation seasons of 1915 and 1916, and are interesting in showing the difference of conditions during the two seasons, there being a corresponding difference in evaporation, but a close agreement in transpiration ratio, as would be expected. The year 1915 was extremely dry, and the flood came down somewhat later than usual in the summer, which caused the length of the growing season to be very much less than its average, due to shortening both at the beginning and at the end. The season of 1916, however, was an extremely good one for irrigation, although the mean temperatures ran somewhat below the 11-year mean for which records are available.

In converting the transpiration ratio, as determined by these experiments, to the actual duty of water chargeable to transpiration, in acre-inches, the growth had to be estimated. Experiments were made in various localities as to the weight of the green cutting and the consequent hay produced; but, in order to use the data throughout the localities in question, average crop figures had to be utilized. Although the different experiments showed from 3 to 5 tons per acre of hay harvested from the Chewaucan Marsh, and from 2 to 5 tons from the Harney Valley fields, an inspection of crop reports showed that the average quantity produced from the former locality was slightly less than 3 tons per acre, and that harvested from the latter

locality was but little more than 1 ton per acre. Therefore, in converting the figures of transpiration to acre-inches, a crop intensity of 2½ tons per acre was used for the Chewaucan Marsh, and 1½ tons per acre for the Harney Valley.

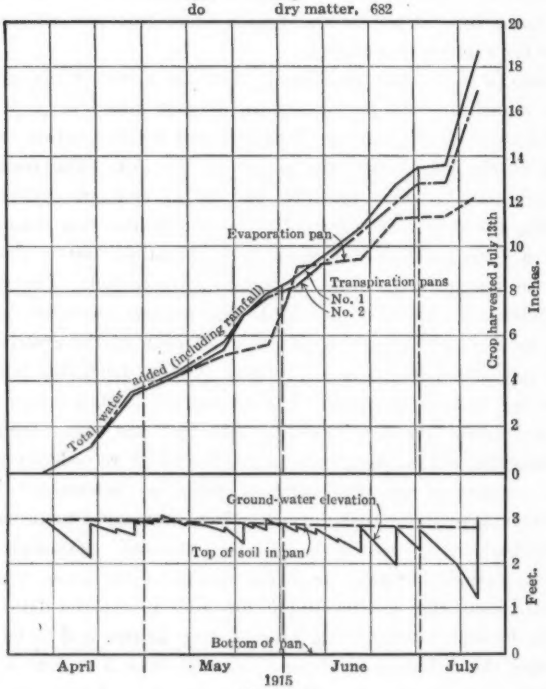

FIG. 15.

Soil Absorption.—When a quantity of water is applied to the surface of a dry soil, it sinks and is absorbed by the soil, traveling downward and laterally until the distribution is such that all is held by

capillarity. When a balance is obtained, the water again begins to travel upward to replace the moisture evaporated from the surface, and so continues until a condition is reached when the quantity of moisture is so slight that no travel will occur. Although the total voids may be equal, in two soils having particles the effective diameter of which is widely different, the storage capacity of the soil of finer texture is the greater, and likewise its resistance to percolation, due to the greater surface tension of the smaller particles. Different plants require different proportions of soil moisture in order to produce the best results. When the percentage of soil moisture drops below certain limits, the roots refuse to take up more, and the plant wilts. Table 11 gives the percentage of moisture below which the plant growth comes to a standstill and the plant wilts.

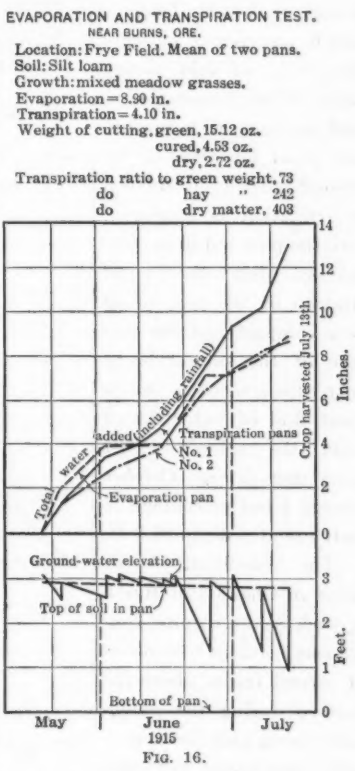

FIG. 16.

As the percentage of moisture required for plant growth exceeds the quantity which will be held by capillary action, it is clear that in permeable soils a balance cannot be reached, as previously stated, but there must be a continuous movement of water downward in irrigation. This is called percolation. If, however, the soil is underlain by an impermeable stratum which prevents a continuous downward motion, the soil moisture may be held above the wilting point without percolation losses.

The foregoing description is given in order to show that soil absorption and percolation act in most conditions and for most crops; it is not given as a statement of the case for the experiments described in the following.

The soil of the Chewaucan Marsh consists of a layer of true peat, from 1 to 4 ft. thick, underlain by a few feet of mixed soil, under which occurs a bed of chalky soil of great depth. The chalky soil is continually saturated, and the ground-water during the non-irrigation season is within a few feet of the surface. During this season, as seen by Tables 5 and 6, an average of more than 8 in. of rain occurs, which offsets evaporation to such an extent as to prevent any great lowering of the ground-water level. As soon as irrigation is discontinued, the peat soil dries very quickly, but the lower stratum of the peat being very compact and the texture of the subsoil being very close, there is not a great deal of water drawn from the subsoil. Post holes dug during October showed a low percentage of moisture at a depth of 3 ft.

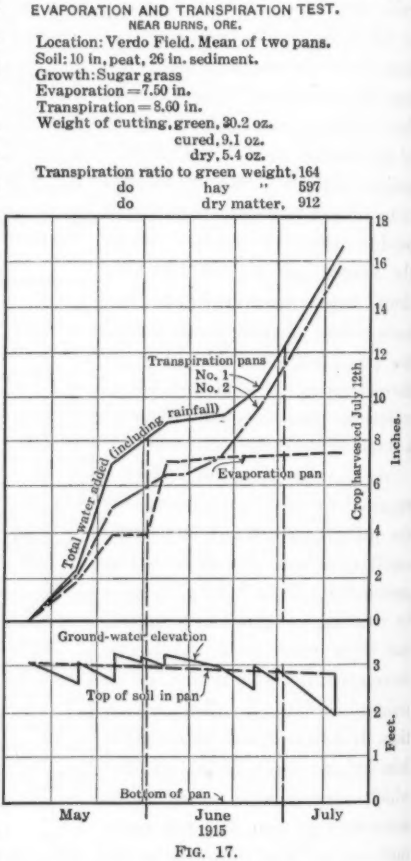

FIG. 17.

The character of the crops on Chewaucan Marsh is such as to require continuous flooding to a depth of several inches above the surface during the irrigation season and the continuous movement of the water during that time. An examination of the nature of the growth on different parts of the marsh, with an analysis of the topographical conditions, shows that any departure from this condition of continuous flooding has an immediate effect on the character of the growth. Wherever the flow of water is checked,

Percentages given by weight, and not by volume.

of water absorbed by the soil, therefore, one must consider, not only a thoroughly saturated soil, but a water cover of sufficient depth to insure a surface velocity sufficient to supply the needs of the beneficial grasses.

To determine the quantity of water which would be absorbed by the soil at the beginning of the irrigation season, the following experiments were performed, and the following calculations made:

First.—The porosity of the soil was determined, roughly, by making an excavation to a depth of 4 ft., and accurately measuring its size. A water-tight box was then constructed having the same cubical capacity as the excavation. After drying the earth taken from the excavation, it was replaced in the box in such a manner as to occupy the same space as it did in place. Water was then measured into the box until the soil was thoroughly saturated, and thus the percentage of voids was determined, and found to be 58 per cent.

Second.—From the writer's previous work in soils of a similar nature, it was found that, with ground-water at a depth of about 8 ft., soil evaporation would be negligible, and, for any depth to ground-water of less than 8 ft., the quantity of evaporation would be proportional to the depth. A similar conclusion was reached by Mr. Lee, in his work previously cited.* With this as a basis, and using the mean monthly temperatures and mean monthly precipitation for the non-irrigation season, namely, from July 1st to March 15th, Table 12, showing the depths to ground-water at different periods,

* *Water Supply Paper No. 294*, U. S. Geological Survey.

FIG. 21.—SINKING TUBE IN SUBSOIL BY DRIVING.

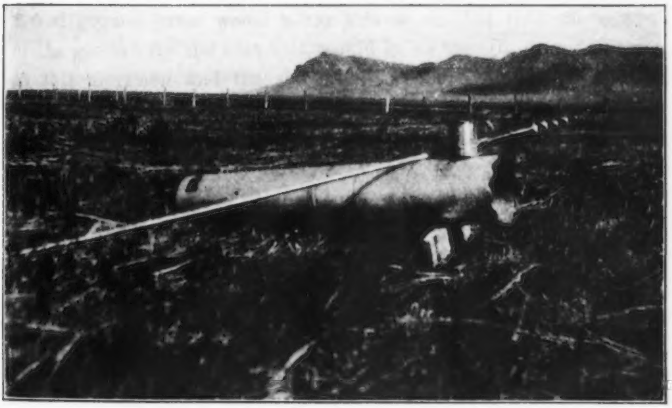

FIG. 22.—APPARATUS USED IN SOIL ABSORPTION TEST.

was computed. In doing this, it was assumed that irrigation would be stopped on July 1st and that the marsh would be uncovered progressively from July 1st to 31st, inclusive—evaporation thus taking place over half the marsh during July.

TABLE 12.—PROGRESSIVE DRYING OF SOIL DURING NON-IRRIGATION SEASON FOR CHEWAUCAN MARSH.

Month.	Evaporation from water surface, in inches.	Per-centage.	Sub-surface evaporation, in inches.	Rainfall, in inches.	Depth to ground-water, in inches.
July	4	97	3.88	0.80	5.50
August	7	90	6.30	0.37	15.35
September	5	82	4.10	0.76	20.85
October	3	77	2.31	0.82	23.33
November	1	76	0.76	1.32	22.63
December	1	76	0.76	0.96	22.88
January	1	77	0.77	1.51	21.26
February	1	78	0.78	1.21	21.03
March 1st to 15th	1	78	0.78	0.52	20.66
	24	.....	20.44	8.27	.....

From Table 12 it is seen that ground-water would reach its lowest depth on October 31st, and that, on March 15th, it would be at a depth of 20.66 in. below ground surface. It is not meant by this that the actual ground-water would be at this depth, but that the condition of the ground for the first 8 ft. would be as though ground-water was at this elevation and the soil was dry above it. The quantity of subsoil evaporation to be replaced at the end of this period is seen from Table 12 to be 20.44 in., less a rainfall of 8.27 in., during the same period, or a net depth of 12.17 in.

As a check on this computation, and also in order to determine the rate of absorption, a special apparatus was devised for making a more accurate test in place. This apparatus (Figs. 14, 21, and 22) consisted of a heavy sheet-iron tube, 5 ft. long and 10 in. in diameter, to the top of which was riveted a heavy band for driving. The bottom of the tube was sharpened to a fluted knife-edge for the purpose of cutting through the sod into the subsoil before beginning to drive. This tube was set up vertically over the place to be tested, and turned with a long lever until it had cut through the sod to a depth of about 12 in. It was then driven with wooden mauls through the soil and into the chalky layer below so as to enclose an area of the original

soil 10 in. in diameter in the water-tight tube. Borings, adjacent to the tube, were made with a soil auger in order that the nature and depth of the soil could be recorded. Water was then measured into the tube with a quart measure, and replenished at stated intervals, the depth of water added being recorded at the time. The top of the tube was kept covered in such a manner that no evaporation could take place. The result of this test is shown on Fig. 23.

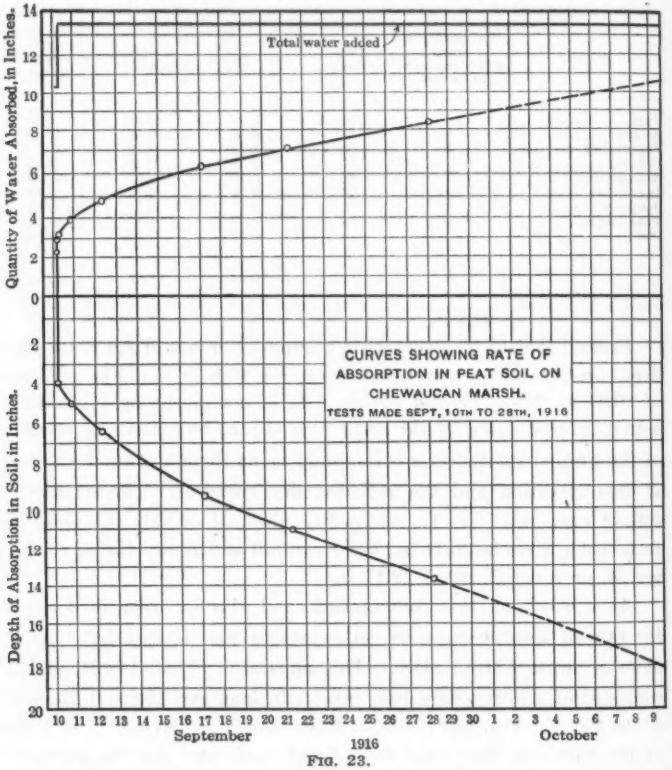

FIG. 23.

It will be noted from the curves on Fig. 19 that the water sinks almost immediately to a depth of 4 in., the rate of absorption then gradually diminishing until a depth of about 10 in. is reached, when the rate of absorption becomes fairly uniform. It will also be noted that the soil requires about 6 weeks to reach a saturated condition.

It is probable that the actual rate of absorption on the marsh is somewhat greater than that shown in the test. During dry weather, the surface of the marsh cracks to some extent, the cracks extending some distance into the soil. These cracks lead the water to a good depth immediately, and allow it to distribute laterally as well as vertically. In the test, however, no crack was included within the limits of the cylinder sunk into the soil, and, therefore, this lateral distribution would be eliminated.

In Harney Valley, the soil in general is of a different nature. The writer found, by borings made in October, 1916, about 2 months after harvest time, that the soil was quite dry for a depth of 2 or 3 ft., gradually increasing in moisture below that depth until a saturated condition was reached at a depth of about 5 ft. Soil samples were taken at various locations, and a porosity of from 27 to 52% was found. The subsoil is such that considerable percolation occurs, both vertically and laterally, the latter being very noticeable in the growth of grasses and the deposit of alkali on areas not irrigated. It was found that lateral percolation would be apparent at a distance of 500 ft. from the nearest place where water was applied on the surface.

As the rainfall from October to March is generally sufficient to offset soil evaporation, and as the soil in test holes was found to be dry for a depth of 3 ft., the quantity of moisture which would be absorbed in the 3 ft. would vary, according to the texture of the soil, from 10 to 18 in., or an average of about 14 in.

Percolation and Run-Off.—One of the principal losses of water in irrigation, and likewise the hardest component to determine, is that of percolation and run-off. As heretofore stated, it is impracticable to supply to the soil the exact quantity of moisture needed for plant use and evaporation and still keep it in the right condition of moisture to obtain the best growth. The best yields per acre are obtained in soils which have a natural drainage, that is, where the soil itself is underlain by a more open subsoil, permitting the excess waters to percolate freely and be carried to some watercourse. Where underground drainage is not obtained in this manner, it sometimes happens that the excess water applied in irrigation accumulates in the soil and gradually raises the water-table until harm is done to the plant life. In these cases, it becomes necessary to put in an

artificial system of drainage, consisting either of open-drain ditches or buried tile drains leading to some watercourse where the excess water may be discharged.

In the case of the growths considered in this paper, however, no harm is done by lack of under-drainage; on the contrary, the plants thrive in a saturated soil, and, in the case of sugar grass, even require moving water on the surface of the ground It is a decided benefit, therefore, to have an impermeable subsoil and a lack of under-drainage, as this eliminates losses by percolation which would otherwise occur.

On the Chewaucan Marsh, as heretofore stated, the subsoil is of an impermeable nature, and there is practically no loss from percolation, but, as the sugar grass requires a saturated soil and free water moving over its surface, and as the configuration of the marsh is such that an absolute uniform depth cannot be obtained, the depth must be such as to cover the high points. The least mean depth which will cover the marsh and submerge it as a whole was found to be from 4 to 6 in., at which the depth would be practically zero at the high points.

The least velocity at which the surface water needs to move, in order to prevent it from becoming stagnant and changing the character of the growth, has never been determined. A determination was made of the velocity under present conditions, both by calculation from physical conditions and by observation of the current as it exists, and this velocity was used to compute the quantity necessary for run-off. It is possible that works might be established by which this velocity could be made less without harm to the plants, but this is not known, and it is very doubtful if the velocity could be diminished much without producing damaging conditions.

Using the velocity thus obtained and the cross-section of the water cover at various points on the marsh, the writer calculated that the loss of water by surface run-off was about 23 in. in depth over the acreage irrigated.

As before stated, the nature of the soil, the growth, and the topography of the country in the Harney Valley are much different from that on the Chewaucan Marsh. The surface soil in Harney Valley consists of a medium silt loam on the surface, with occasional areas of peat soil, the whole being underlain with a sedimentary silt having particles with an effective diameter of about 0.5 mm. The valley is cut up considerably by watercourses, dams in the latter serving to

deliver the water to the land, the excess being dispersed by run-off, by longitudinal percolation to Malheur Lake, and by lateral percolation to the streams below the dams, and in these it continues to the lake.

Excepting for the sugar-grass areas, continuous surface flooding would not be necessary, from the standpoint of growth; but, considering the fact that both soil and water are quite alkaline, such flooding is necessary to keep this alkalinity from becoming detrimental to growth. Outside of sugar grass, the growths found in the valley thrive about equally under continuous flooding and intermittent flooding sufficient to keep the soil saturated. However, as the latter is strongly impregnated with alkaline salts, any condition which will cause the soil water to be brought to the surface and evaporated, will cause a deposit of the salts, which is destructive to vegetation. By continuous flooding, the salts are prevented from being deposited, and the growth continues until the final shutting off of the water, when they are deposited up to the time when the soil is dry, but too late to damage the growth to any extent. The salts deposited after the irrigation season are washed off with the first rush of water in the spring, and this allows the new growth to start.

The loss by longitudinal percolation is slight. As the effective diameter of the soil particles is about 0.5 mm., and the surface slope toward the lake is about 0.08%, the rate of percolation, longitudinally, would be only about 9 in. per day; but, as the valley is traversed by deep watercourses to which the water may percolate and be carried off directly, there are slopes as great as 4 or 5%, which would cause velocities of percolating water as great as 50 ft. per day. Even at this rate, however, percolation is small, as compared with surface run-off, and as there is great likelihood of error in calculating either one, it was considered in this investigation as included in the run-off.

Conditions of run-off were much the same as on Chewaucan Marsh, except that the water was not collected into a single channel on its discharge from the irrigated area, as in the case of the Chewaucan Marsh, and, therefore, no check could be made on the calculations as to the quantity of run-off. The country was also much more irregular than the surface of the marsh, and thus many knolls were left without surface cover, and, on the areas affected, the depth had to be greater than in the case of the marsh, in order to cover as much ground as possible. For this reason, the surface velocity of the irrigating streams

was greater than on the Chewaucan Marsh, although the surface slope was somewhat less. It is safe to provide a run-off of at least 40% of the total delivery in order to protect against alkali. This would give about 24 in. of depth over the irrigated area.

Conclusion.—Though the investigation herein described was made necessary by the system of irrigation and a class of growth about which little was known, the same method of analysis may be used on any class of irrigation and any growth. By a study of the plant and its needs in regard to soil moisture, the method of application of the water may be determined; and by a study of soil and climatic conditions, an analysis of the use of this water may be made, which will vary in accuracy according to the extent of the investigation. It is not claimed by the writer that this method is always superior to that of direct trial; nevertheless, it is useful in some cases where that is impracticable, and in other cases it will give results which, taken in conjunction with the duty obtained by direct trial, will aid in the elimination of losses, the improvement in yield, and the betterment of irrigation methods.

In conclusion, the author wishes to acknowledge the assistance of Carl J. Rhodin, M. Am. Soc. C. E., to whom is largely due the work of comparison of evaporation data; and of Professor P. B. Kennedy, of the University of California, whose classification of the different plant growths encountered and study of the reasons for their occurrence were invaluable.

The writer has purposely omitted many of the factors which aided him in arriving at his conclusions, and even much of the detail in regard to the conclusions themselves, as the investigations described herein were for use in certain litigation which has not yet been brought entirely to a close. The purpose of this paper, therefore, is merely to show the methods used, and any figures given will be considered as merely exemplifying such methods and not as final determinations of results.

DISCUSSION

Mr. Versluys.

J. C. VAN REIGERSBERG VERSLUYS,* ESQ.—The subject treated in this paper is of great interest to Java, the country from which the speaker has just come.

Java, one of the larger islands of the Netherlands East Indies, has a population of about 38 000 000, and the people live almost entirely on rice. The density of population is very great as the island is only about one-third as large as California. The birth rate is very high, and it must be expected that the population will be doubled within the next 40 years.

The area planted with rice amounts to about 4 000 000 acres, of which 2 500 000 acres are irrigated. The average yield of irrigated fields is about 1 000 lb. of eatable rice per acre. All rice is grown on small farms, most of them of from 1 to 2 acres. The rice farmer is a light-hearted, easily satisfied man, who does not work hard, but brings up his family on $60 a year. Of course, this cannot go on, for as civilization advances, the cost of living will continue to rise—the American moving pictures, for instance, have become a necessity in the larger cities.

As almost all the virgin soil is now in use, the Netherlands Government has been induced to undertake extensive investigations with reference to the possibilities of increasing the rice crop in accordance with the needs of the people. Of course, as the best and most easily irrigated holdings were taken up long ago, the main proposition now is to make the best use of what is still left, and improve the existing systems. The average yield of non-irrigated farm lands is from 50 to 55% of those which are irrigated.

Artificial fertilizers have been tested; they increase the output considerably, but have proved too expensive. The natural fertilizers are in the soil itself, which is generally volcanic. Irrigation helps to supply nitrogen, but phosphorus is the most important element in rice.

Many questions dealt with by Mr. Hammatt are also of the greatest importance in Java. There is not enough water to provide all the later irrigation systems with the conservative quantity of from 20 to 30 in. per year. The latest conclusion arrived at is that the duty of the water cannot be dealt with separately from local geological conditions.

The speaker regrets very much not being able to go further into details, but he has no notes with him to which he can refer.

Mr. Rockwell.

W. L. ROCKWELL,† M. AM. SOC. C. E. (by letter).—In the field of irrigation engineering the economic duty of water, a subject regarding which comparatively little is known, is of prime importance. In Texas

* Member of the Royal Institute of Engineers, The Hague, The Netherlands.

† San Antonio, Tex.

Mr. Rockwell. this study has been progressing for more than 3 years, and has included the application of water to cultivated and uncultivated fields, with and without crops, and daily sampling at intervals of from 5 to 30 days, to depths of from 6 to 12 in., both before and after irrigation. During the same periods, an investigation of the evaporation from water and soil surfaces has been conducted. The many and various details are made as comprehensive, and the work is done as accurately, as conditions will permit.

Mr. Stevens. J. C. STEVENS,* M. AM. SOC. C. E. (by letter).—The author defines the duty of water, as used in his paper, to be "the quantity which can be applied with the greatest efficiency, under given conditions, for the production of crops."

It appears to the writer that the author's study merely resolves the quantity of water applied in practice into its component parts, without touching on the matter of efficiency at all.

Doubtless, the author concludes that the duty given is the efficient one, the data forming the basis of his conclusion being withheld for the very excellent reasons given in his closing paragraph.

The total quantity necessary for the crops in question, and its component parts, in the terms used by the author, are given in Table 13. To these quantities must be added the losses incident to the transportation of the water to the point of use, and storage losses, if any. Hence, the duty given in Table 13 appears to be very low indeed.

TABLE 13.

Component.	Harney Valley.	Chewaucan Marsh.
(1) Soil Moisture	14.0 inches.	12.2 inches.
(2) Soil Evaporation	10.8 "	10.5 "
(3) Plant Use	8.0 "	14.5 "
(4) Soil Losses	24.0 "	23.0 "
Totals	56.8 inches.	60.2 inches.
Acre-feet per acre	4.73	5.00

Good yields of alfalfa, wherever the climatic conditions favor its growth, can usually be secured with about half the foregoing quantities, net, on the land. Moreover, alfalfa is generally conceded to require more water than any other general crop growth in the United States.

The questions naturally arise: Is the land thus situated, where the total water supplies are limited, being put to its highest use? Would it not be far better to put twice the area under cultivation with the same water supply?

* Portland, Ore.

Mr. Stevens.

It is seen that the largest single component of the water duty is "Soil Losses". This is treated under the caption "Percolation and Run-off," from which it appears that these particular grasses require flowing water during the growing period, in order to produce aeration and carry off the alkaline salts.

The author states that, in Harney Valley, except for the sugar grass areas, continuous surface flooding is required in order to avoid alkalinity, and not for plant growth. In other localities the accepted method of removing injurious alkaline salts is by drainage. If open ditch drainage will obviate the necessity of continuous flooding, is not that the first point of attack, in order to determine the efficient use of water in this locality?

The writer knows the two areas in question only by reputation and cursory examination. He knows that in both valleys there are large areas of land and small quantities of water, and it would seem that the only justifiable use of the limited water supply is one that will put the greatest number of acres under cultivation and create the greatest number of homes.

The writer awaits with interest the remaining data which the author undoubtedly has obtained. For example, it would be interesting, indeed, to know the total quantity of water consumed in the two valleys during the two seasons in question. On Chewaucan Marsh this could have been, and perhaps was, determined with ease by measuring the total inflow and outflow on the upper and lower marshes at the three constricted portions of the valley. This consumption should be comparable with the sum of the first three component parts of the water duty previously given, and, in the writer's belief, will be considerably less than the 37.2 in. which the author's analysis seems to indicate as the required quantity.

In Harney Valley the problem of determining the consumption is not so simple, but, doubtless, natural facilities were found where it could be determined for certain representative areas.

The writer is delighted with this paper. Mr. Hammatt has attacked an old problem in a novel manner, and has arrived at results which contain an element of surprise. It is to be hoped that, when the time is propitious, he will give the Engineering Profession the benefit of all the data he has gathered.

The foregoing discussion was written after a careful reading of the paper, but without analyzing the processes by which the author reached his conclusions. The writer, however, has since had occasion to inquire more deeply into the subject, and has also secured additional data, relative to the use of water on Chewaucan Marsh, which throw some extremely interesting side-lights on Mr. Hammatt's conclusions.

Mr. Stevens.

As these data are matters of public record, and appear in publications of the U. S. Geological Survey, the writer feels that there can be no breach of ethics in using them.

In Table 13 the writer gave the component parts of the duty as fixed by Mr. Hammatt. These component parts will be considered in the order in which they are treated by the author.

Evaporation.—The writer begs to call the author's attention to the results of a 6-year record of evaporation from a standard U. S. Geological Survey floating pan in the Klamath River, at Keno, Ore., 1904-1909.* This record was not used by the author.

After making some minor adjustments for missing winter records, the 6-year average evaporation and average monthly temperature given in Table 14 has been used by the writer.

TABLE 14.—MONTHLY EVAPORATION AND TEMPERATURE RECORD AT KENO, OREGON.

Average of 6 Years, 1904-09; Elevation, 4 090 Ft.

Month.	Evaporation at Keno.	Air Temperature at Klamath Falls.
January	0.50	32.0
February	0.60	35.6
March	1.09	38.0
April	3.13	46.4
May	4.14	49.9
June	5.16	57.4
July	6.44	69.2
August	6.46	66.1
September	4.65	59.2
October	2.26	50.0
November	1.07	40.0
December	0.80	30.8
The year	36.30	47.9

This record for 1909 is simultaneous with that at Ady used by the author; yet the evaporation at Keno was considerably less than that recorded at Ady. Moreover, the evaporation for the Ady station, as given by the author in Table 8, is not the Ady record.

The record for the Ady station for 1909 is given in "Working Data for Irrigation Engineers", by Moritz, whom the author quotes as his authority. Moritz takes his figures from Professor Bigelow's Abstract of Data No. 4 entitled "A Provisional Statement Regarding the Total Amount of Evaporation by Months at 23 Stations in the United States, 1909-10."

* *Water Supply Papers Nos. 177, 213, 251,* and *271,* U. S. Geological Survey.

Mr. Stevens.

Table 15 is a comparison of the figures as given by Professor Bigelow and Mr. Moritz with those used by the author; also a comparison of the Ady and Keno records for 1909, with corresponding temperatures.

It appears from Table 15 that the evaporation from the Ady pan was 15.5 in. more than from the Keno pan. The reasons are apparent when the physical characteristics of the two exposures are compared.

Keno Pan.—3 ft. square, 18 in. deep, floating in Klamath River, a stream about 400 ft. wide; mean depth, 8 to 10 ft.; discharge, 1 000 to 3 000 sec-ft.

Ady Pan.—4 ft. diameter, 10 in. deep, floating in stagnant shallow water of a borrow-pit alongside of railroad embankment.

The water temperatures of the borrow-pit were much higher than those in Klamath River, which chiefly accounts for the increase in evaporation.

TABLE 15.—Comparison of Evaporation Records at Ady and Keno, Oregon, 1909.

* Estimated.

The results of experiments on evaporation at the Denver Laboratories by Mr. R. B. Sleight,* show that:

1.—Evaporation from flowing water is 8% greater than from still water, all other factors being equal.

* *Journal of Agricultural Research*, July 30th, 1917.

Mr. Stevens.

2.—An increase in water temperature produces corresponding increases in evaporation, as follows:

2° increase in temperature produces 10% increase in evaporation.

4° increase in temperature produces 19% increase in evaporation.

6° increase in temperature produces 30% increase in evaporation.

10° increase in temperature produces 55% increase in evaporation.

16° increase in temperature produces 100% increase in evaporation.

The increase at Ady is 41%, which would be produced by a mean water temperature increase only 8° greater than that at Keno. The Ady record, however, was not used by the author in deducing the evaporation for Chewaucan Marsh.

It has been shown that the correct figures for evaporation at Ady are already 40% too high, yet the author increases them by 7½% for differences in elevation, and then calls attention to the fact that they fit his figures deduced from Owens River, California.

Now examine the author's deduced evaporation for Chewaucan Marsh, in which a 4-year record from Owens River near Independence, Cal., was used. He first increases the evaporation at Independence by 16% for a corresponding difference in barometric pressure.

The author states "that evaporation at different elevations is in inverse proportion to the barometric pressure." He then gives the pressures at Independence and Chewaucan as 26.0 and 25.35 in., corresponding to elevations of 3 775 and 4 410 ft., respectively. Here is the equation:

$$\text{Evaporation at Elevation } 4\,410 = \text{Evaporation at } 3\,775 \times \frac{26\,00}{25\,35}.$$

This is an increase of 2½%, and not 16%, as stated by the author. The increase in elevation is 16.8%, which is probably what he had in mind.

In the paper cited by the author, "A Study of the Depth of Annual Evaporation from Lake Conchos, Mexico," by Messrs. Duryea and Haehl*, Subsidiary Conclusion (*e*) states their conclusions as to the relation between elevation, mean temperature, and evaporation, thus:

"(*e*)—In the Great Plateau Region, and at elevations above sea level of 600 to 5 000 ft. and monthly mean temperatures higher than 70° Fahr., the increases in the evaporation depth at any given mean temperature are directly proportional to increases in elevation; but at monthly mean temperatures lower than 70° Fahr., and at the lower elevations, the evaporation depth at any given mean temperature increases with the increase in elevation, but less rapidly than in direct proportion."

* *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 1829.

Mr. Stevens.

The writer positively denies that any such relation as that just quoted, or as modified by the author, has been established in the paper cited or elsewhere. A perusal of the paper in question and of the discussions which follow it will convince the most credulous that no such relation exists. As a matter of fact, such information as we have on the subject indicates the opposite tendency, namely, a decrease in evaporation with an increase in altitude.

An article by Samuel Fortier, M. Am. Soc. C. E.,* gives the results of experiments on Mt. Whitney, Cal., to determine the influence of altitude on evaporation. Evaporation records were obtained at stations varying in elevation from 4 500 to 14 500 ft.

Briefly stated, the results of this investigation indicated a consistent and steady decrease in the evaporation from the lower to the higher elevations, that at 10 000 ft. being 40% less than that at 4 500 ft. Professor Fortier concludes:

"While these [non-uniformity of exposure] doubtless influenced the results to some extent it is safe to conclude that altitude was the controlling factor."

It is the writer's belief, however, that the controlling influence, in the Mt. Whitney experiments and elsewhere, is water temperature, and that it is just as easy and just as logical to attempt to establish a relation between the water temperatures of Owens River and Chewaucan Marsh and their respective altitudes, as it is between the evaporation and elevation of the two places.

Moreover, if the evaporation varies inversely as the barometric pressure, it would be infinitely great in a vacuum, which is an absurdity.

After correcting the Owens Valley records for elevation, the author proceeds to correct them for mean monthly temperatures. This process can only be defended on the theory that air temperatures are some definite index of water temperatures. That there is a broad general relation between air and water temperatures is admitted, but when the great complexity of conditions, such as origin of water (*i. e.*, springs or surface), exposure, depth, currents, atmospheric conditions, etc., are considered, the relation must necessarily be so broad and general that the author's use of it cannot be defended on any logical basis.

By way of illustration, it is interesting to note the effect on evaporation and plant transpiration of the volcanic eruption of Mt. Katmai, Alaska, during the early part of June, 1912. This effect was noted by Messrs. Briggs and Shantz during their experiments to determine the water requirements of plants at Akron, Colo.†

These gentlemen increased the water consumption of plants during 1912, as observed by them, 30% in determining mean values from the

* "Evaporation Losses in Irrigation," *Engineering News*, September 19th, 1907.

† "The Water Requirement of Plants," *Journal of Agricultural Research*, October 15th, 1914, by Lyman J. Briggs and H. L. Shantz.

Mr. Stevens.

3-year record, 1911, 1912, and 1913. They also show that evaporation from a free water surface during June, July, and August, 1912, was 22% lower than the average of 1911 and 1913. These reductions in both evaporation and plant transpiration were charged directly, by them, to the volcanic disturbance cited.

When such remote causes are seen to exert such powerful influences, it would seem that the results obtained by the author are absurd. He increases the Owens Valley records 16% for elevation (our present knowledge indicates they should be reduced, if corrected at all); next, he reduces them for temperature (with no basis of fact); then he increases them 33% for shallow water (an utterly unfounded assumption); finally, he decreases them by varying quantities for plant growth (purely guesswork); and he confidently states that the mean evaporation on Chewaucan Marsh, from March 15th to June 30th, is 10.51 in.

Transpiration.—The author states that the mean daily rate of transpiration on Chewaucan Marsh was 198% of the green weight of sugar grass on June 27th, which was the 105th day of its growth, and that the plant was fully grown. Is there any reason to assume that the plant stops transpiring water at maturity? It would be just as logical to say that man did not require food and water after he was fully grown. Certainly, transpiration continues until the crop is harvested, which, the writer infers from Figs. 15 to 20, and elsewhere in the paper, is not done until some time in August.

The determination of the 198% is based on 15-min. weighings during 10 hours of a single day in the season. The remainder of the 24 was determined by guess. The weight of green matter was "considered" to increase uniformly during its period of growth. The author states that:

"Although the experiments seemed to show that the rate of loss immediately after cutting was from 40 to 50% greater than after a period of 15 min. * * *"

this was ignored. Yet the whole process is founded on the theory that the rate of transpiration immediately after cutting is a measure of the rate during growth.

Furthermore, the diagram, Fig. 10, indicates that the so-called cured hay was still losing moisture at the rate of 10% per day. Surely his average crop of 2½ tons per acre is not based on a 3-days' curing. Hay is not usually measured for crop statistics until after 30 days or more in the stack. If measured in this way, it may lose as much as 80% of its green weight.

Cured hay was found to contain 40% of moisture. Hence, it is found that in Chewaucan Marsh the transpiration ratio for green hay was 30% of that of cured hay, and that of cured hay was 60% of that of dry matter.

Mr. Stevens.

Now examine the transpiration figures for the Harney Valley, given in each of the diagrams, Figs. 15 to 20, inclusive. The results are given in Table 16.

TABLE 16.

Crop.	Transpiration Ratio to:		
	Green weight.	Cured hay.	Dry matter.
Fig. 15—Sugar and mixed grasses	123	409	682
" 16—Mixed grasses	73	242	403
" 17—Sugar grass	164	597	912
" 18—Sugar and mixed grasses	122	402	669
" 19—Mixed grasses	71	238	398
" 20—Sugar grass	104	346	577

The figures in Table 16 show that, with the exception of Fig. 17, the ratio for green weight is 30% of that of cured hay, and that of cured hay is 60% of that of dry matter. In other words, the cuttings from the several pans were neither cured nor dried. Instead, the green cuttings were weighed, then a factor, determined on Chewaucan Marsh, 100 miles away, on a bright day in June, was used to find the transpiration ratio for different varieties of grasses in the Harney Valley, and the results were given to the Engineering Profession as scientific data.

As the author does not give his figures for plant use, in inches, the writer had to do some guessing. He "guessed" that the author's figures for the transpiration ratio of dry matter more nearly represented that of cured hay, and that the plants transpired water until harvested. The average of the author's ratios for dry matter for the Harney Valley was 600:1, and the writer "guessed" that 650:1 would be about right for Chewaucan Marsh. In this manner the 8 in. and 14½ in. for Harney and Chewaucan, respectively, given at the beginning of this discussion were found.

Soil Absorption.—The writer wishes to protest against the misconstruction placed on the results obtained by Charles H. Lee, Assoc. M. Am. Soc. C. E., as shown by the following quotation from the author:

"From the writer's previous work in soils of a similar nature, it was found that, with ground-water at a depth of about 8 ft., soil evaporation would be negligible, and, for any depth to ground-water of less than 8 ft., the quantity of evaporation would be proportional to the depth. A similar conclusion was reached by Mr. Lee in his work previously cited."

Mr. Lee's experiments were made in order to determine the soil evaporation from the floor of the Owens River Valley, and that evaporation includes transpiration of the native salt grass. His results give the soil losses from the sandy clay loam soils, but Mr. Hammatt has applied them to peat.

Mr. Stevens.

Now, there are peats and peats. The 25th Annual Report of the Vermont Agricultural Experiment Station, 1911-12, contained the following data:

Turfy peat	weighing	7-16	lb.	per.	cu.	ft.,	air-dried.
Fibrous "	"	15-42	"	"	"	"	"
Earthy "	"	25-56	"	"	"	"	"
Pitchy "	"	38-65	"	"	"	"	"

The author gives the saturation content of peat soil as 274% by weight, of which 253% is free moisture. He also states that the Chewaucan peat soil had 58% voids. These figures give a weight of 14.3 lb. per cu. ft. of air-dried soil, which indicates that the Chewaucan soil would probably fall under the "Turfy peat" classification. The writer's general knowledge leads him to believe that this peat is of a coarse, rooty structure, with a large capacity for water, but with low capillary properties compared with the clay loams. If this is true, the height to which water will rise by capillarity is very limited indeed.

The limit of the rise of water by capillarity in certain soils is given in Table 17.*

TABLE 17.

Soil.	Limit of rise.	Time required.
Sandy soil, Stanislaus County, Cal.	17 in.	6 days
Gila River alluvial soil	47 "	125 "
Silt soil, Ventura, Cal.	50 "	195 "
Adobe soil, Alameda County, Cal.	46 "	195 "

The writer has seen no similar data for peat soil, but it is very doubtful if water will rise by capillarity more than 2 or 3 ft. When the ground-water falls below the limit of capillary rise, soil evaporation ceases.

On the assumption that the limit of capillary rise in peat soil is 30 in., instead of 96 in., it appears that the author's quantity of sub-soil evaporation, as indicated in Table 12, is 50% too high.

The writer is unable to understand Fig. 23. Apparently, 13½ in. of water were put in the tube on September 11th. Thereafter, at stated intervals, the recession of water in the tube, or the depth to ground-water, was measured. Apparently, at the close of the experiment, the soil had absorbed 10.5 in. of water, which resulted in lowering the ground-water 18 in. In other words, the porosity of the unwatered soil in the tube was 58 per cent. Were the dotted lines merely drawn to confirm the previous determination? Does the diagram really show anything more?

* As given by Professor Hilgard, in "Soils," The Macmillan Company.

Quantity of Water Actually Consumed on Chewaucan Marsh.—The quantity of water actually consumed is the crux of the whole matter. If the author's processes are logical, his deductions as to the water consumption should conform to the actual consumption, as indicated by the difference in flow at the upper and lower ends of the marsh. The writer has stated (page 253) that: Mr. Stevens.

"This consumption should be comparable with the sum of the first three component parts of the water duty previously given, and, in the writer's belief, will be considerably less than the 37.2 in. which the author's analysis seems to indicate as the required quantity."

Since that was written, *Water Supply Paper No. 410* has come to hand, and it gives the results of stream measurements in the Chewaucan River Valley for the seasons of 1914 and 1915. The writer has also secured the unpublished results for 1916 and 1917, which may be had by any one on application to the Director of the U. S. Geological Survey, Washington, D. C.

The map, Fig. 1, should be consulted in order to understand the situation properly.

Three gauging stations were maintained on Chewaucan River:

1.—The Paisley Station, which is above all important irrigation diversions, 2½ miles up stream from the Town of Paisley;
2.—The Narrows Station, at the constricted portion of the marsh; and
3.—The Hotchkiss Ford Station, just below the marsh.

The following stations were also maintained at the diversion points of ditches watering the alluvial fan at the head of the marsh:

Conn Ditch, irrigating 600 acres;
Smalls Creek, irrigating 2 417 acres, including 1 209 acres under the Bageley Ditch;
Jones-Innis-ZX Ditch, irrigating 2 118 acres.

There are 14 300 acres of marsh and about 6 200 acres of upland watered between the Paisley and the Narrows Stations, of which 5 235 acres are accounted for by the ditches just mentioned. There are also 7 800 acres of marsh between the Narrows and Hotchkiss Ford Stations.

In order to determine the quantity of water consumed on the marsh, it is necessary to deduct a portion which is diverted to irrigate the uplands. A considerable portion of the diverted water finds its way by percolation and waste to the marsh.

In Table 18 only 40% of the water diverted has been considered as consumed; the remaining 60% being returned to the marsh. The diversions for the 965 acres unaccounted for have been neglected. This gives the consumption on the marsh the benefit of all doubt.

Mr. Stevens. The period of consumption, given by the author, March 16th to June 30th, inclusive, has been used.

TABLE 18.—Water Consumption on Chewaucan Marsh.

	March 16th to June 30th, Inclusive.				
	1914	1915	1916	1917	Average.
Flow at Paisley, in acre-feet	94 600	39 510	77 200	93 640	76 240
Deduct for consumption on 5 235 acres of upland —40% of measured diversions	8 000*	7 900	8 200	7 600	
Net flow to marsh	86 600	31 610	69 000	86 040	
Flow at Narrows, in acre-feet	70 800	11 260	43 200	64 180	
Consumed on 14 200 acres of marsh	15 800	20 350	25 800	21 860	
Depth, in feet	1.10	1.42	1.80	1.52	1.46
Flow at Hotchkiss Ford, in acre-feet	59 250	2 160	31 360	51 180	
Consumed on 7 800 acres of marsh	11 550	9 100	11 840	13 000	
Depth, in feet	1.48	1.16	1.52	1.67	1.46
Consumed on 22 100 acres of marsh	27 350	29 450	37 640	34 860	
Depth, in feet	1.23	1.33	1.70	1.57	1.46

* Records incomplete—estimated.

The period of record includes two years of abundant supply, 1914 and 1917, and also one low year, 1915. The consumption during 1916, when the author's investigations were made, is seen to be the highest of record, although the water supply was about the average. The supposition is, therefore, that the crop conditions during the period of his investigation were somewhat better than the average. If this is not true, the conclusion is inevitable that the hay lands received too much water. At all events, it is obvious that the crops received all the water that was necessary for their growth.

Before making a comparison of the author's computed requirements and the water actually consumed, it is only just to reduce the quantity for plant consumption previously given by the writer, to that represented by the author's deduced transpiration ratio of 347 lb. of water per pound of cured hay. Making this correction, the requirements as computed by the author are:

	Chewaucan Marsh.
1. Soil moisture	12.17 in.
2. Soil evaporation	10.51 "
3. Plant use	7.64 "
4. Soil losses	23.00 "
Total depth	53.32 in. = 4.44 ft.

Now, the first three of these items should be comparable with the measured consumption, if the author's hypotheses and deduc-

tions are rational. That they are not, is evident from the following: Mr. Stevens.

	Author's deduced requirement.	Actual measured consumption.
Water consumption on 22 100 acres of marsh for soil moisture, soil evaporation, and plant use, in feet.....	2.53	1.46
Error	73%	....

The author's Item 4, "Soil Losses," is treated under the caption, "Percolation and Run-off." He states that there is no percolation, but that the marsh hay will not thrive unless the ground is completely covered with running water during the period of growth, and further fixed the necessary quantity as 23 in. of depth.

The actual run-off from the 22 100 acres of marsh is that measured at Hotchkiss Ford, as given in Table 19.

TABLE 19.—RUN-OFF AT HOTCHKISS FORD, FROM MARCH 16TH TO JUNE 30TH, INCLUSIVE.

	Acre-feet.	Depth, in feet.
1914.....	59 250	2.67
1915.....	2 160	0.10
1916.....	31 360	1.42
1917.....	51 180	2.31
Average.....	.....	1.62

It is inconceivable that all the run-off is necessary. If this were true, there could scarcely have been any crop at all in 1915, as the run-off was only 1 in. Furthermore, during 1916, while the investigations were under way, it is seen that the author's requirement is 35% greater than the total supply available for this purpose. Little more need be said. The actual figures refute the author's processes and conclusions.

S. T. HARDING,* ASSOC. M. AM. SOC. C. E.† (by letter).—Mr. Hammatt has presented the results of considerable detailed work on some of the factors affecting the use of water for meadow lands. The irrigation of native grass meadows and pastures by methods involving more or less continuous application of water is found in many localities throughout the West where climatic conditions make the production of crops of higher value uncertain. The nature of the field methods used makes it difficult to segregate the use of water on small areas for experimental purposes without introducing artificial conditions, and it is noticeable that State and Federal agencies have done very little experimental work on such crops. Mr. Harding.

* Berkeley, Cal.

† Now M. Am. Soc. C. E.

Mr. Harding.

To meet these conditions, Mr. Hammatt adopts a method which gives him control of some of the elements observed. In any experimental work involving the duty of water, two conditions must be secured in order to get results which can be applied to field conditions. The first of these is to be certain that the conditions of the experiment are similar to those in the fields; the second is that all essential elements are subject to control and measurement. The use of small volumes of soil in tanks satisfies the second of these considerations, but it may be open to question in regard to the first, although Mr. Hammatt has reduced the differences from field conditions to a minimum.

In many respects the practice described by the author resembles that used in rice irrigation in California. The water is held on the land during a large part of the growing season and is subject to similarly varying evaporation and transpiration losses during the different stages of growth of the rice. Owing to the method of preparing rice lands in checks, the waste or run-off is much less than that estimated by the author for sugar grass. As far as the writer can ascertain, no results of similar observations on rice under field conditions have been published, although the lack of percolation on many rice lands offers an opportunity for observation of evaporation and transpiration during the different stages of growth.

The duty of water depends, not only on the quantity required by plants for their growth, but also on the quantity which it is necessary to use under reasonable standards of practice in order that that required for direct use can be made available to the plants at the time needed. This latter requirement may result in the use of quantities considerably in excess of the direct crop requirements where the conditions are such as to cause large surface waste or deep percolation losses. The only way in which the efficiency of application can be determined is under field conditions. It is noticeable that the detailed work by the author only covered 60% of the total recommended use, an estimated allowance of 40% being included for surface waste.

Mr. Hammatt adds 33% to his estimated evaporation from a deep tank in order to ascertain the evaporation from a thin sheet of water such as occurs on the marshes. The results secured by R. B. Sleight, Jun. Am. Soc. C. E., at Denver, Colo.,* indicated an evaporation 11% greater in June from a tank 3 in. deep than from one 5.75 ft. deep, and of 12% less in October. Mr. Sleight's tanks were more comparable than those used by Mr. Lee, on which Mr. Hammatt's estimate was based. Mr. Sleight found that the placing of a shallow tank above ground gave a higher evaporation, by more than 20%, than a similar tank set in the ground. Mr. Lee's shallow tank was set largely above the ground.

The author's statement, that "the ratio of the quantity of water transpired to the quantity of plant matter produced * * * is within

* *Journal of Agricultural Research*, July 30th, 1917.

such close limits as to be to a certain extent measurable", and the results given relative to transpiration for various standard crops, are, in the writer's opinion, more likely to be misleading than helpful, if an attempt is made to apply them in general irrigation practice. When yields may be varied 100% by various fertilizer treatments for soils receiving equivalent moisture, as under humid conditions, it is evident that the "transpiration ratio", so called, gives little guidance as to the proper duty of water. Mr. Harding.

Mr. Hammatt states that his previous observations had corroborated Mr. Lee's conclusion that, with ground-water at a depth of about 8 ft., soil evaporation would be negligible, and, for any depth to ground-water of less than 8 ft., the quantity of evaporation would be proportional to the depth.

It is the writer's opinion that the results presented by Mr. Lee* do not warrant this as a general conclusion, and that the results of other published experiments show that the depth from which water will be drawn to the surface depends very materially on the texture of the soil. Unfortunately, descriptions of the soil, as given in the reports of some of such work, are too indefinite to permit of making full use of the results.

In order to compare observations of soil evaporation made in different localities, some means of correlating climatic factors is required. The evaporation from a water surface is probably the best single unit for this purpose. In Fig. 24 a number of such observations have been assembled, the evaporation from the soil being expressed as a percentage of that from a water surface at the same locality.

Five of the results given are from Mr. Sleight's work at Denver, reference to which has been given. Mr. Sleight defines the texture of the material by the size of the opening of a screen, in inches, such that 60% of the material passes and 40% is retained. The tanks used were 2 ft. in diameter, and the results have been compared with the evaporation from a water surface in a tank of similar size. The coefficients which should be used in reducing the evaporation from soils in tanks to that from large areas are not known; some limited experiments by Mr. Sleight indicate a more marked variation from soils than from water. The four coarser materials are river-bed sands; the fine sandy loam is from the soil at the laboratory.

The results given in *Bulletin 52* of the Wyoming Experiment Station were secured in 6-in. tanks containing soil cores taken in the field. The texture of the soil is not given.

In his work, Mr. Lee states that No. 2 tank was filled by replacing the soil as found with the stratification as existing in the adjacent soil.

* *Transactions*, Am. Soc. C. E., Vol. LXXVIII (1915), p. 148.

Mr. Harding.

Tank No. 3 had a layer of black loam soil under the sod, the remainder of the soil being mixed. It is stated that Tanks Nos. 4 to 7 contained a mixture of clay, soil, and fine sand, a rather general description. A curve based on Tanks Nos. 4 to 7 only, omitting Tanks Nos. 2 and 3, which do not plot consistently with the others, would, if extended, indicate a zero evaporation for this mixed soil when the water-table

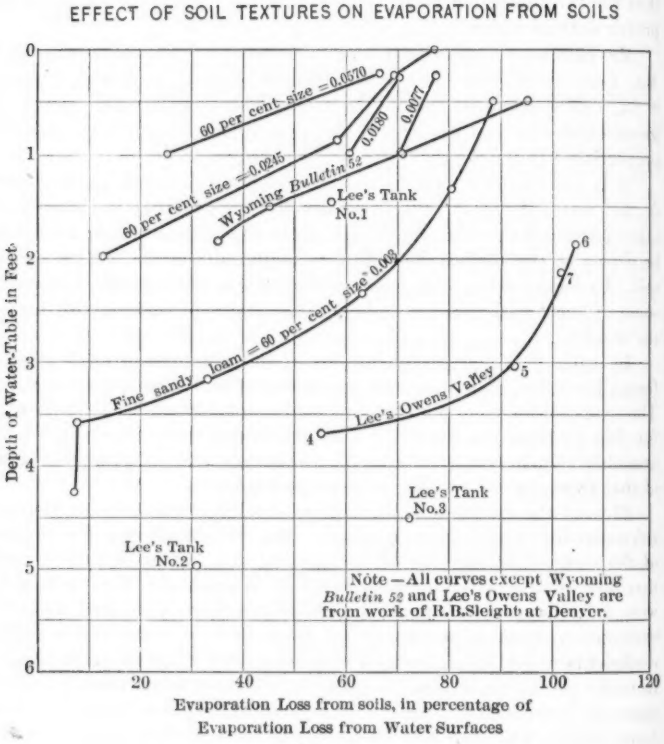

FIG. 24.

is somewhat more than 4 ft. below the surface. Mr. Lee's soil tanks were 7½ ft. in diameter, his deep-water tank was 3½ ft. in diameter, and would have a coefficient of 0.83, according to Mr. Sleight's experiments. This coefficient was applied to the evaporation from the deep-water tank, as the larger size and growth of sod would probably give a small correction for the soil tanks.

Mr. Harding

Mr. Lee's Tank No. 1 was without sod, but had on the surface 2½ ft. of clean river sand of mixed sizes. The results for June to September, 1910, are given in *Water Supply Paper No. 294*, and are plotted on Fig. 24.

From the curves on Fig. 24 several conclusions may be drawn. The most evident one may be the need of more thorough investigations of this subject, giving more consideration to the texture and arrangement of the material. It also appears, however, that the depth from which moisture will be drawn to the surface, and the extent of evaporation from different depths, varies very materially with the texture of the soil. For coarser materials, the depth from which evaporation will occur may be less than 2 ft.; data are lacking on soils of heavy texture. The fine sandy loam at Denver indicates little loss for depths of more than 5 ft. on such medium to light soils.

The results of Mr. Lee's work are the only ones given for a soil supporting vegetation. The increased proportion of loss from his Tanks Nos. 4 to 7 may be due to the heavier texture of the soil or to the additional effect of the salt grass roots in drawing water for transpiration, the description of the soil is too indefinite to enable one to compare it with the other experiments.

The results in general indicate that in coarse material, with the water-table 3 in. below the surface, the evaporation will be less than from an adjacent water surface; with medium or heavy soils it may equal or exceed such loss from a water surface.

The evaporation from soils is often an important item in matters involving the loss from marshes, the salvage in water which may be effected by drainage, the water requirement of such crops as those included in Mr. Hammatt's work, and in the saving that may be secured in cultivation with soil mulches. The field of investigation is one requiring much careful experimental work and analysis of results, the data available are limited, and there is much opportunity for additional work.

Mr. Hammatt.

W. C. HAMMATT,* M. AM. SOC. C. E. (by letter).—The writer is pleased with the discussion brought forth by his paper, but somewhat disappointed that so little of it had to do with the methods used, and that the main part merely bore on the results obtained on the particular work cited. The intention of the paper was to introduce for discussion and criticism, with a view to improvement in method, the principle of analytical experiment as applied to the determination of the duty of water in irrigation. The two campaigns carried out by the writer in Lake County and Harney County, Oregon, were merely given as examples, with apologies for defects in the methods used, in some cases due to lack of time and necessity for hurried results.

* San Francisco, Cal.

Mr. Hammatt.

The discussion by Mr. Versluys is interesting in showing results obtained in rice culture in Java, rice being the one cultivated crop comparable in any way with the wild grasses on which the writer's experiments were made. The writer, however, is somewhat surprised at the results, as the average yield—1 000 lb.—is only about 40% of the average yield for California. Possibly this is due to the extreme rainfall conditions in Java, the average annual rainfall varying from 72 to 175 in., distributed throughout the entire year. This would have a tendency to increase the quantity of straw at the expense of the grain, allowing an insufficient dry period for maturing the grain. It is probable that if the rainfall were properly distributed no irrigation whatever would be needed, as the total annual rainfall is in excess of the requirement for rice.

The average quantity of water used in the Sacramento Valley in California for rice culture is about 99 in., the extremes ranging from 53 to 179 in. Of this only about 1½ in. was precipitation during the irrigation season. The irrigation season, by the way, is from the middle of April to the last of October, ranging from 147 to 189 days.

The work of investigation in Texas, mentioned by Mr. Rockwell, will doubtless be of great interest, and the writer hopes that full descriptions of the methods used and results obtained will be published for the benefit of the Profession. The writer judges the sampling at various depths and intervals to be for the determination of the distribution of moisture in the soil both during the penetration of the irrigation water and its consumption by evaporation and transpiration.

Mr. Harding's criticism of the addition of 33% to deep-water evaporation rates on account of shallow water is well founded. Mr. Lee's experiments do not justify this as a fixed percentage, and the quantities given by Mr. Sleight are probably more correct for the conditions obtaining on Chewaucan Marsh during the irrigation season, if the increment is considered as due only to the water depth. There are other conditions obtaining on the marsh—which are not encountered in the pan experiments—which tend to increase the evaporation rate, so that, in the aggregate, the 33% increment is probably justified. The condition having the greatest influence is that of the dense plant growth, causing the water to be drawn up the outside of the stalks and the evaporation to be accelerated.

The exception taken by Mr. Harding to the writer's statement that "the ratio of the quantity of water transpired to the quantity of plant matter produced, * * * is within such close limits as to be to a certain extent measurable", is justified on the basis that he makes in his explanatory statement. The writer, however, only intended to apply it to cases where other conditions were equal. In the case of forage crops, where the plant food is taken largely from the air, it holds very closely

through a wide range of soil conditions. A seed crop, however, will have a great variation in transpiration ratio, depending on the soil fertility. Mr. Hammatt

As Mr. Stevens makes specific objections to several of the results obtained by the writer, his various points will be answered in the order in which they occur in his discussion.

The writer had no knowledge of the 6-year record of evaporation at Keno, Ore., at the time of the investigation on Chewaucan Marsh, or, for that matter, at the time his paper was written. Inquiries at the Oregon Agricultural College, the U. S. Geological Survey, and the U. S. Weather Bureau succeeded only in unearthing the Ady record. Had he known of the Keno record, he would have made use of it in preference to the Owens Valley record.

As for the discrepancy between his tabulation of the Ady record and that published by Moritz, the writer did not, as stated by Mr. Stevens, quote Moritz as his authority, except for those months specifically mentioned. The writer's figures were obtained from photostat copies of the original reports, furnished by the Weather Bureau. As for the difference between the results of the Ady record and that at Keno, the writer cannot agree with Mr. Stevens that it was due to difference in water temperature.

The writer cannot believe that the water temperature has in itself any great influence on the rate of evaporation, within the limits of temperatures usually occurring. According to well-known physical laws, a definite volume of air, at a particular temperature and density, will absorb a definite volume of water vapor, this being dependent on the temperature and density. As saturation is approached, the rate at which the vapor will be absorbed will of course diminish, hence the effect of humidity. If the water is in thin sheets, spray, or capillary form, evaporation will be accelerated. To liberate 1 lb. of water vapor, about 966 B.t.u. must be absorbed by the water. In natural conditions, this heat is absorbed from the atmosphere, which is thus the controlling factor.

Mr. Sleight, in his experiment, placed an electric globe in some of his pans to control their temperature. He thus made the experiment entirely dissimilar to the natural condition of evaporation, supplying the heat necessary to evaporate the water by an artificial heating plant. The fact that the evaporation was greater in the heated than in the unheated pan merely proved that a greater quantity of heat was being supplied to it, which fact was corroborated by the rise in temperature of the water. Under natural conditions, the temperature of the water surface is controlled by the evaporation, rather than the converse. Mr. Sleight did not state in his report the size of the electric globes used, nor the time they were kept lighted. A 40-watt lamp will produce about 3 260 B.t.u. per 24-hour day, sufficient for the evaporation of 3.38 lb. of water, which, in the tanks used in the experiment, would be

Mr. Hammatt.

equivalent to 2.06 in. in depth. A considerable portion of this heat, however, is dissipated through the walls and bottom of the tank.

Also, in the experiments to determine the effect of flowing water on evaporation, the conditions of the experiment were totally unlike any natural conditions. The water was circulated with a centrifugal pump, and, from an inspection of the single record published, the work done by this pump was sufficient to raise the temperature of the water 10 degrees. Although a correction was made for the difference of water temperature by comparison with pans heated by electric globes, it is extremely doubtful whether the relative absorption and evaporation from the heat generated by the bulbs would be the same as from that produced by the working machinery. It is the writer's opinion that, under similar conditions, there is likely to be greater evaporation from flowing than from still water, due to surface agitation and to friction with the atmosphere, but this will be an indeterminate variable, and due rather to the relative movement of the wind and water than to the absolute motion of either.

Mr. Stevens states that "the correct figures for evaporation at Ady are already 40% too high, yet the author increases them by 7½% for differences in elevation." If the figures of the U. S. Geological Survey at Keno are accepted, as against those of the Weather Bureau at Ady, which is questionable, the difference is 29% instead of 41 per cent. The effect of elevation, or atmospheric density, however, seems to be open to some question.

Soon after the publication of this paper, the writer had his attention called to the statement that "evaporation at different elevations is in inverse proportion to the barometric pressure." It was immediately apparent that the principle was stated improperly, and he wrote a short discussion correcting the error and making additional explanations of the matter. It was decided, however, to withhold this discussion until the writer submitted his closure; the substance thereof is given below. The statement should have read as follows:

"The writer has always believed that, other conditions being equal, the evaporation will vary with a function of the difference in barometric pressure at the different points."

The writer based his opinion and belief on the fact that the boiling point of water lowers as the barometric pressure decreases, requiring a smaller application of heat to vaporize the water at higher elevations. It is true that the data published in the paper by Messrs. Duryea and Haehl are insufficient to establish this beyond question, but a platting of the data in Table 17 of that paper shows that the curve of evaporation relation coincides with that of barometric relation between the limiting elevations of 2 500 and 5 000 ft. As Dr. Fortier's experiments ranged from Elevation 4 500 to 14 500 ft., they are nearly all above those quoted by Messrs. Duryea and Haehl, so that it is possible that the

Mr. Hammatt.

relation may change at the higher elevations. The writer's confidence in the physical law quoted is such, however, that he would rather be inclined to study with care all the conditions attending the Fortier experiments in order to ascertain if there was not a possibility of other influences being strong enough to counteract that of elevation.

The specific correction for the influence of elevation on the rate of evaporation by comparison with the evaporation records in Owens Valley was made from a study of the figures in Table 20 showing the barometric differences, considering the barometric pressure at sea level as 30 in. of mercury.

TABLE 20.

Elevation, in feet.	Barometric height, in inches.	Drop in barometer from sea level.	Percentage relation to barometric height at Elevation 3 775.
2 000	27.79	2.21	— 44.8
3 000	26.74	3.26	— 18.5
3 775	25.96	4.04	.....
4 000	25.74	4.26	+ 6.4
4 090	25.65	4.35	+ 8.6
4 410	25.34	4.66	+ 16.3
5 000	24.77	5.23	+ 30.6

The writer makes no claim that the various coefficients used in correlating the evaporation records at Independence to conditions existent on the Chewaucan Marsh are absolute. He maintains, however, that their principle is established by physical laws, and that their application is a matter of engineering judgment in connection with careful observation of field conditions. This is particularly true with the deduction for plant cover, characterized by Mr. Stevens as "mere guesswork." The physical law is that saturated air will take no additional water vapor, and must be replaced by dry air if evaporation continues. The fact, determined by the writer by inspection at various periods of growth, was that, as the grass grew higher and spread, the movement of air was more and more restricted. Although the straight-line variation may not be justified by experiment, it is by logic, until experiment shall have given a better one.

In this matter it is interesting to note the actual results of the soil pan evaporation tests in Harney County, as shown in Figs. 15 to 20, inclusive. These are tabulated in Table 21, from which it will be noted that, although the season averaged shorter than that assumed for the Chewaucan calculation, the total evaporation was greater. This may be explained by the fact that the season falls about a month later in the Harney County tests than in the Chewaucan calculation, a part of the hotter months—July and August—being included in place of March and April, used in the Chewaucan figures.

Mr. Hammatt.

TABLE 21.

Location.	Year.	Length of Season.			Evaporation loss, in inches.
		Begins.	Ends.	Days.	
Wickes Field	1915	April 8	July 13	96	12.10
Frye Field	1915	May 18	July 15	58	8.90
Verdo Field	1915	May 5	July 12	68	7.50
Wickes Field	1916	March 30	August 4	127	15.78
Frye Field	1916	April 13	August 4	114	15.62
Verdo Field	1916	March 28	August 3	128	17.33
Mean				98.5	12.87

In Fig. 25 are platted the heights of the growth in the various pans in the Harney County tests during the season of 1916. The uniformity of growth is apparent from this diagram, justifying the straight-line reduction of evaporation for plant cover and the uniformity of transpiration increase.

Mr. Stevens states that plants continue to use water after maturity, and compares the use of water by plants with the consumption of food by man, with a fine disregard for the laws of mechanics. The food consumed by man is transformed into mechanical energy, which is dissipated in work or motion. Plants perform no such work, and their food goes entirely into growth. When a plant reaches maturity, it ceases to take in water through its roots, and loses in drying a large portion of that already taken, making hay while still standing. There is even a claim of a slight backflow into the earth, causing the loss of some of the food value, for which reason it is considered advisable by stockmen to cut for hay slightly before maturity, though the writer is somewhat skeptical as to this, and believes that the greater food value of hay cured after cutting over that cured standing is probably due to other causes.

Mr. Stevens is evidently not familiar with the practice of curing hay. It is not usual to leave the hay on the ground more than 48 hours, and where possible it is stacked within 72 hours after cutting. Stockmen consider that the hay loses in food value if left longer without stacking. Moreover, after putting in the stack, it not only ceases to lose weight, but gains in weight by absorption from the atmosphere. Mr. Stevens' inference that the ratios of green weight, cured weight, etc., used in the Harney Valley experiments were taken from the test made at Chewaucan Marsh is also in error, the cutting from each of the pans having been cured for 48 hours and weighed at intervals during the period.

Mr. Hammatt.

The writer, after considerable study, is unable to comprehend Mr. Stevens' "guessing" paragraph, so assumes that it was put in to add humor to his discussion.

Regarding the matter of soil absorption, Mr. Stevens' information is correct as to the nature of the peat, and also in regard to its low capillary limit. The layer of actual turfy peat, however, is quite thin, being from 8 to 12 in. in depth, followed by a mixture of peat in the white volcanic soil, described in the paper as underlying the marsh, and gradually changing to the unmixed white soil. Although the turfy peat has a low capillary limit, it shrinks and cracks in drying, allowing free access of air to the underlying soil, which has a much higher capillary limit. Test holes bored in September, 1916, two months after the discontinuance of irrigation, showed that the soil was practically dry for a depth of 2 ft. About thirty holes were bored at this time,

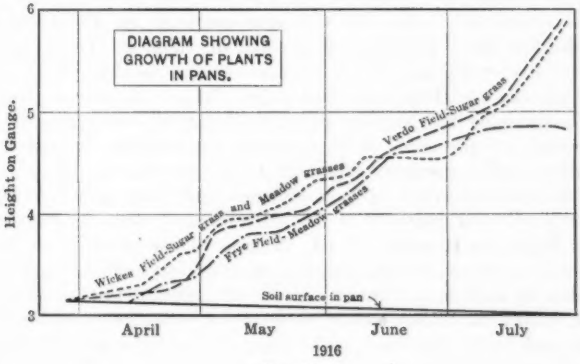

FIG. 25.

representative of the entire area of the two marshes. As the subsoil has been found to be practically impervious, the contained water at the close of irrigation must have been lost by capillary rise and surface evaporation.

In the later test of the absorption capacity of the soil, Mr. Stevens correctly interpreted Fig. 23 as showing the putting of 13.54 in. of water into the tube on September 10th, 10.15 in. being introduced at 4.30 P. M. and 3.39 in. at 5.05 P. M. The top of the tube was covered to prevent evaporation, and measurements of the lowering of the water surface were made at intervals thereafter. The curve above the line, showing the depth of water absorbed, was platted from the observations up to September 28th, the broken line being produced at the same rate, which had been uniform for the previous two weeks. The curve below the line, showing the depth of penetration of the absorbed water,

Mr. Hammatt.

was platted for the first 6 in. from tests taken previously, the final measurement being taken on September 28th, when the tube was removed and the core examined. The line between these points, as well as its dotted extension, was made from the percentage relation found from the measurements taken.

We now come to the interesting part of the discussion, the attempted application of run-off data at the three main gauging stations on the Chewaucan River to determine the actual consumption on the marsh. The arguments used remind one so strongly of those appearing in *Northwest News,* a promotion sheet published by the real estate firm promoting the Paisley Project, and the data presented have such a similarity to those presented by the engineer for that contestant in the litigation, that the reason for the rather acrimonious nature of Mr. Stevens' discussion may be inferred. In fairness, the records of the case should have been quoted, showing the presentation of data to the effect that, although the measurements at Hotchkiss Ford included all water running off the marsh, those at the Government gauging station did not include all that running on the marsh, that the water passing the Hotchkiss Ford gauge did not all pass the Narrows, and that passing the Narrows did not all pass the Government gauge. Testimony was presented showing a very considerable water-shed with a high run-off percentage tributary to the marsh, the run-off therefrom being intercepted by a drainage canal along the edge of the Upper Marsh and delivered at the Narrows, and along the edge of the Lower Marsh, to Hotchkiss Ford. A creek of considerable size, known as Moss, or Avery, Creek, empties on the Upper Marsh and is not included in any measurements given of inflow, while another, still larger, known as Willow Creek, is used for irrigation near the Lower Marsh, and was, by the breaking of dams, diverted into the Lower Marsh without appearing in any measurement except that of Hotchkiss Ford. The effect of these is very apparent by comparison of the daily hydrographs at the three stations, the run-off at Hotchkiss Ford often exceeding that at the Narrows during rainfall periods, and that at the Narrows increasing by a much greater percentage than that at the Government Station.

Since this paper was written, the Court has handed down a decision based on the evidence produced at the trial, allowing a duty of 3.9 ft., or 46.8 in., somewhat smaller than that claimed, but about double that advocated by Mr. Stevens. This decision has been upheld by the Supreme Court, an appeal having been denied. The difference between the duty claimed, 60.1 in. and that allowed by the Court, 46.8 in., or 13.3 in., was doubtless due to the Court's opinion that the full run-off claim of 23 in. was not indisputably established.

The writer acknowledges the impossibility of establishing the exact quantity necessary to insure the proper movement of water over the

Mr. Hammatt

marsh, due to the irregular flow of the river. The total run-off measured at Hotchkiss Ford, shown in Table 19, certainly did not represent the necessary run-off, as a material part of it was run-off from the adjoining water-shed during storms, and did not go on the marsh at all. The actual necessity for the movement of the water is well established, however, an analysis of the plant growth on the marshes having been made by Professor P. B. Kennedy, of the University of California, and it being shown by survey that whenever the flow of the water was impeded by knolls or ridges, the valuable grasses were replaced by tules and cat-tails, and wherever the flooding was intermittent, as on the tops of knolls, covered during the periods of greatest flow but uncovered during periods of lesser flow, the predominant growth was blue-joint and fox-tail. As for Mr. Stevens' statement that if the claim of the necessity were true "there could scarcely have been any crop at all in 1915," he is quite right, there having been no crop at all on those parts of the marsh where the water ran on and was consumed without run-off, the only full crop being obtained from the small acreage at the head of each marsh, where the water was first turned on the land and kept running continuously over it. This point was also well established by testimony, and appears in the Court records.

A study of the hydrographs of the various years of record shows in general an excess of water during the early summer, with a falling below the requirement from the middle of May onward. By turning the whole flow over the land and flooding it to a depth greater than was actually needed, the water was held and the uncovering of the marsh delayed beyond the time when it would otherwise take place. It is this which causes the run-off percentage to be so high in some years. For instance, in 1914 there was a very high March and April flood, causing a high run-off for that year. In 1916, the flow of the water was ideal, coming at the exact time and in the quantities needed, causing a low run-off during the parts of the season when in general the run-off is high.

The writer asks the indulgence of his readers for having gone into so much detail in his closure on a paper which was intended—and so stated in the opening paragraphs—to be merely descriptive of methods used, for the purpose of drawing discussion and criticism of these methods, and tending toward improvement in future studies. It was not his intention to make any point of the results obtained, these being of merely local interest. This point is entirely missed or ignored by Mr. Stevens in his discussion, in which he criticizes the writer's failure to touch on the matter of efficiency.

The discussion, however, has enlarged the writer's knowledge by offering him additional food for thought, and enables him to draw the following conclusions:

Mr. Hammatt.

(1).—That laboratory experiments are apt to lead to erroneous conclusions if the exact field conditions are not reproduced. This point was brought out by Mr. Harding. It was to satisfy this condition that the pan experiments in the Harney Valley tests were made in the fields themselves, instead of all together in one place, reproducing the same conditions as to plant cover and water depth in the pan as in the adjoining field. One pan of each set had a portion of the water removed and replaced from time to time, in order to reproduce as far as possible the condition of changing water due to flow on the land.

(2).—That there is a sparsity of evaporation data, and such records as there are lack sufficient completeness of detail to permit comparison. It would be advantageous if all the evaporation work could be conducted by either the Weather Bureau or the Geological Survey, in order to insure uniformity, the pans being run at the principal stations in combination with the other data, in order to have available for every section a record of evaporation as well as of rainfall, run-off, temperature, etc.

(3).—That subsoil losses can only be determined by field experiment on a large scale, and necessary surface run-off can only be determined by long-time observations of results under conditions as they exist.

Paper No. 1429

CEMENT JOINTS FOR CAST-IRON WATER MAINS*

By Clark H. Shaw, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Harry Y. Carson, F. M. Randlett, Walter Pearl, H. G. Moulton, H. B. Lynch, Edward R. Bowen, and George W. Pracy.

Synopsis.

This paper presents the method of making successful cement joints in cast-iron water mains.

A brief history of the use of this joint establishes the fact that this method of construction has long since passed the stage of experiment, and has been proved to be an economic factor in laying such mains.

The process of making the joints is described and illustrated, some experiments in jointing are described, cases showing the strength of cement joints under trying conditions are cited, and data relating to cost, etc., are presented.

About 1886 a cast-iron pipe line for water distribution was laid with cement joints at Redlands, Cal., and in 1891 joints of that kind were used at Los Angeles, Cal., but evidently with questionable results, as the method was not adopted. In January, 1907, Mr. Charles Thornburg, then Superintendent of one of the water companies operating in Long Beach, Cal., decided to try cement joints for a 16-in.

* Presented at the meeting of April 18th, 1917.

cast-iron pumping main, and instructed his foreman of construction, Mr. F. M. Shrode, to conduct some experiments.

No definite process was outlined to the foreman, but his experiments and practice in repairing steel riveted water mains under pressure, by using a dry mixture of neat cement in caulking the bands around these pipes, gave him an idea that a moist cement could be caulked into the bell solidly, and would produce the results desired. It was probably Mr. Shrode, who, by this experiment, finally perfected the joint and used it in the construction of the entire line. When this line was completed and put into service, working under a static head of about 190 ft., several places showed some seepage, particularly at the lower end of the line, where the work was started, and it was decided to re-caulk these joints at the first opportunity; it was noticed, however, that the moisture was gradually drying up, and the seepage finally ceased.

Cast-iron construction was then abandoned by this company until 1911. During that year the works came into the possession of the municipality, and the writer was appointed Engineer of the Water Department. After looking into the merits of the cement joint, as used on this 16-in. pumping main, it was adopted as the proper method of construction, and since that time it has been used throughout the entire system.

Long Beach now has 60 miles of cast-iron water mains, ranging from 4 to 24 in. in diameter, laid with joints of this type. All these pipes are under pressures ranging from 40 to 80 lb. per sq. in., and are giving perfect satisfaction.

Method of Making the Joint.

In making the cement joint, the pipe is placed and spaced in the usual manner. A thin backing of the best dry jute is used instead of oakum, as the jute is free from oils and grease (which should be avoided). A Portland cement, conforming to the specifications advocated by the American Society for Testing Materials, is used. The dry cement is placed on a piece of canvas (usually a cement sack ripped open), and moistened just so that when thoroughly mixed by hand (Fig. 1) it will be of such a consistency that when gripped tight it will hold the form of the hand (Fig. 2), and when dropped 12 in. it will crumble (Fig. 3). The canvas containing the cement is placed

under the bell, and the cement is tamped into place by hand with a caulking iron until the bell is about half full (Fig. 7). It is then caulked with heavy blows until the cement is thoroughly packed in the back of the socket. This process is continued until the bell is packed solid out to the face (Fig. 8). A small bead of neat cement in a plastic condition is then put on, using the caulking iron as a trowel (Fig. 9). As soon as the initial set of the cement in the bead has taken place, the joint is covered with earth to protect it from the air and sun. In back-filling, the excavated material is always settled with water, which helps to cure the exposed portion of the joint.

The bead is essential, in the writer's opinion, as the cement packed in the bell is so dry that without protection it would absorb moisture from the water used in settling the trench, and it is believed that, should the joint develop seepage when the pressure is put on in the main, the cement, being dry, would expand and aid materially in keeping the joint tight.

Experiments on cement joints constructed without the bead showed that, 24 hours after completion, they absorbed water readily. In cases where seepage has developed and has subsequently stopped, it is assumed that the dry cement absorbed the moisture from the inside, expanded, and filled the seepage pores.

About 20% of the cement is wasted by falling off the canvas or being thrown out by the caulker. If any dust or earth from the trench falls on the canvas or in the cement, it is immediately taken out, together with enough cement to make sure that the remainder is clean. In mixing the cement with water, care is taken that there shall be no lumps in the material, no matter how small. If any cement is left on the canvas when a joint is completed, it is used on the next joint, provided the work is continuous, otherwise new batches are made. Special blunt caulking tools are used (Fig. 4).

The joint is allowed to stand 48 hours before the pressure is turned on and the main is put into regular service. Cement joints have been used with satisfactory results, however, 12 hours after completion, but this is not considered safe practice. Pressure tests are never made by the writer prior to putting a main into service.

At San Diego, Cal., a pressure test was made by caulking a 6-in. cast-iron tee, one side of the tee being filled with a plug and each of the two ends filled with short lengths of cast-iron pipe with plugs caulked in the ends. As the pieces of pipe caulked in the tee were scrap ends

cut from other pipes, they had no bead on the joint end, and, notwithstanding the fact that the joint was made with smooth pipe, it took a pressure of more than 300 lb. per sq. in. to force the pipe out. The test was made about 48 hours after the joint was made.

In another test, made at Winnipeg, Man., three lengths of 6-in. pipe were laid with four cement joints, on January 13th, 1916. After 6 days, pressure was put on the pipe, in increments of 25 lb., and the joints were found to show no leakage or moisture, up to 125 lb. At 150 lb. one joint showed moisture on the surface of the cement.

On January 24th another test was made, and at one joint moisture appeared at 175 lb. On January 31st this joint showed moisture with 200 lb., and also on March 15th, with a pressure of 255 lb. This joint was the weakest of the four. The pressure was kept on the pipe about one-half hour in each case.

Fig. 5 is a section of a joint made with a cut piece of pipe, and shows the position of the jute and the cement when there is no caulking rim or bead on the end of the pipe (as in the San Diego test). The cement bead, as shown in Fig. 5, was made larger than usual, and covers the entire face of the bell, though normally it covers only about one-half.

The strength and rigidity of the cement joint are shown by the following instances where cast-iron mains have been subjected to severe tests: A new trenching machine was being tested by a sewer contractor in Long Beach, Cal. It operated parallel with and 5 ft. from a 6-in. cast-iron water main, with cement joints, which had been laid in January, 1915. The trench dug by this machine was 3 ft. wide and 18 ft. deep. Some time before noon on February 1st, 1915, the side of the trench next to the water main caved in, leaving about 40 ft. of the pipe hanging and supporting about 2½ ft. of earth on top of it. This condition was not reported until the next morning, and at nine o'clock braces were put in to support the pipe. The main was under a pressure of about 65 lb. per sq. in. at the time. There was not the slightest seepage from any of the joints as a result of this strain.

Again, in June, 1915, 94 ft. of 4-in. cast-iron pipe with cement joints fell into a sewer trench, as the result of a cave-in under conditions similar to those just described. This pipe was under a pressure of about 55 lb. per sq. in. At one end it broke at a service connection;

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

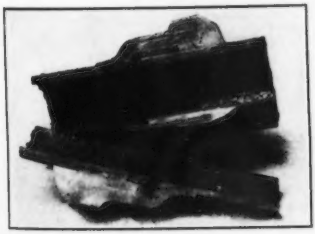

FIG. 5.

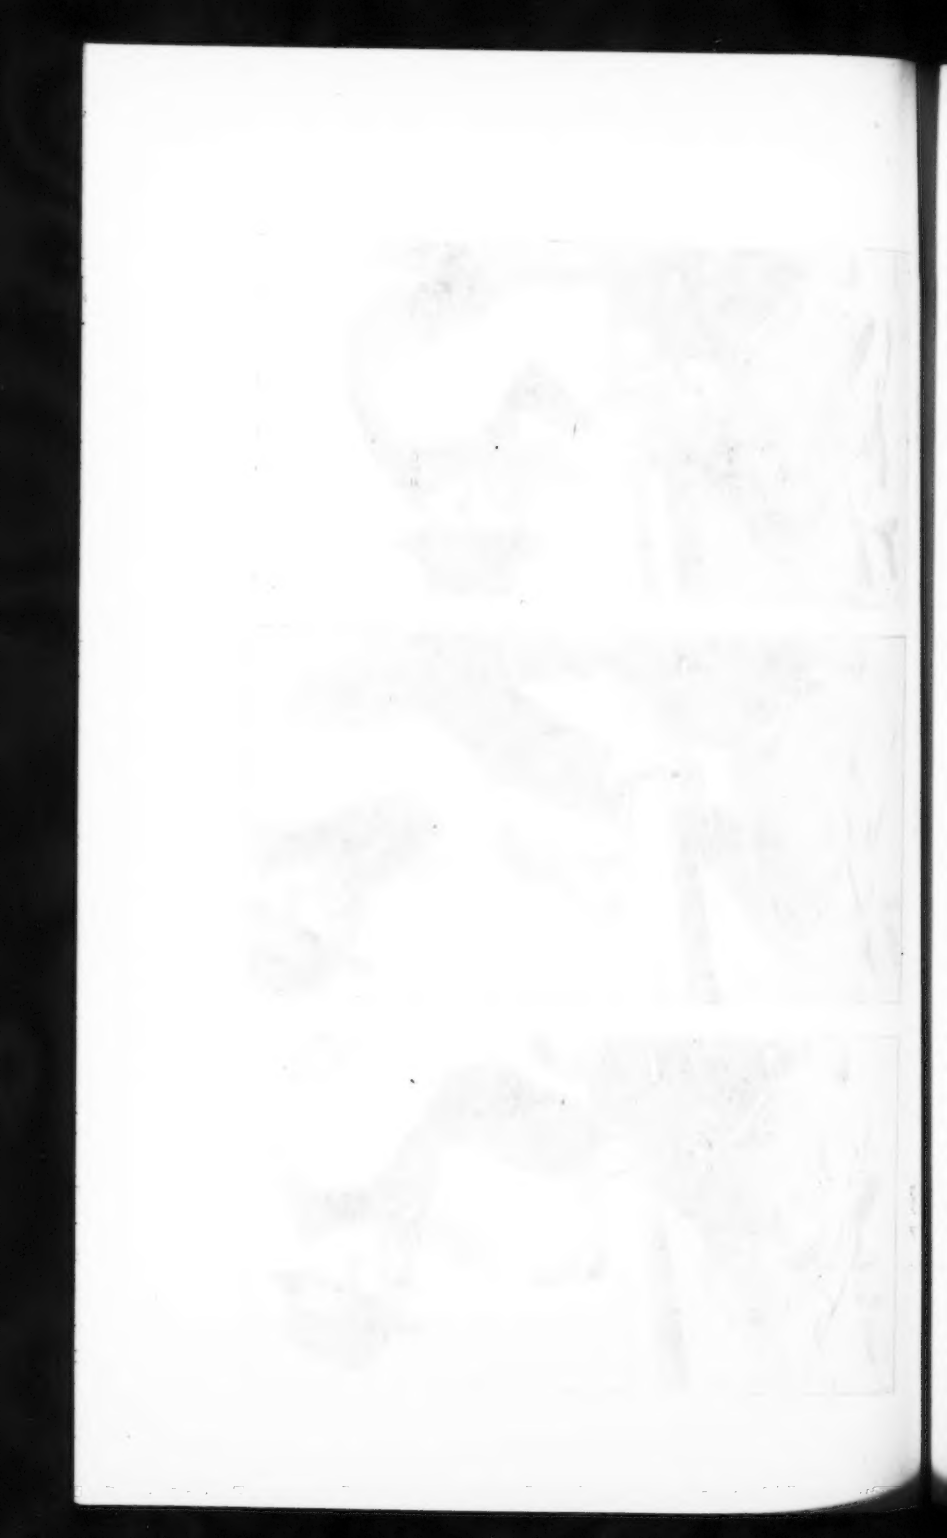
FIG. 6.

FIG. 7.

FIG. 8.

FIG. 9.



at the other end it broke near the spigot end of a pipe, about 8 in. from the joint, letting the whole 94-ft. section fall into the trench. In this case every cement joint remained intact. This line had been laid in March, 1913.

Several thousand feet of 8 and 10-in. cast-iron water mains with cement joints have been laid in made ground, the fill being silt from the dredging of harbor channels; also several thousand feet of 8-in. cast-iron pipe have been laid in fine beach sand; all are giving perfect satisfaction. An 8-in. cast-iron main with cement joints was laid in filled ground (the soil being clay) with only 6 in. of covering above the pipe when the line was put in service; the fill was then completed to 18 in. above the top of the pipe, and was rolled with a 14-ton steam road roller, without causing the slightest seepage in any of the joints. The rolling was done preparatory to paving the street in which the pipe was laid. This was a very severe test of the merits of the cement joint. At the time this rolling was done, had any seepage developed, it would have been readily detected, as the whole line was within 3 ft. of the edge of the fill. The fill was completed to a width of 80 ft., 3 months later, leaving the pipe 12 ft. from the center of the street.

In several instances a cast-iron main laid with cement joints has settled 3 in., or probably more, in loose or filled ground, without developing any leakage. In fact, there is only one case that the writer can recall where the cement joint was not satisfactory. This was in a 6-in. cast-iron main on a dock, about 3 ft. from a railroad track. Many joints in this pipe have developed seepage, and some have small pin leaks, but the leakage is not considered serious enough to warrant closing down the line for re-construction. This failure may be due to faulty construction, as the pipe was laid when the making of cement joints was in its infancy. However, the main is situated so that it cannot be entirely covered.

Removing Cement-Jointed Pipes.

Fig. 6 shows a completed joint. The cement joint can be taken apart in a very simple and economical way. The pipe is uncovered about one-half, or a little below the center. At the joint where the original bell-hole was dug, the trench is usually made wider on the sides (but not deeper under the pipe), in order to permit the caulker to work at the joint. The upper half of the joint is cleaned out with

a cape-chisel; then, with tripod and blocks, the free end of the pipe is raised until the lower half of the joint breaks free from the bell. The pipe seldom has to be pulled out of the bell, as it nearly always works itself out as the free end is lowered. If portions of the cement stick to the spigot end of the pipe, or fail to be entirely crushed in the bell, it is a very simple matter to clean out the bell with a cape-chisel, or knock the cement from the spigot with a hammer.

On occasions, after a joint has been cemented tight in the line, it is necessary to cut it out entirely (such as for laying a valve on its side; turning a tee or Y in another direction; adjusting a tee to conform to or meet a grade; avoiding a sewer connection or any other unforeseen obstacle). Table 1 has been compiled from records of the actual time spent in doing such work.

TABLE 1.—TIME REQUIRED FOR ONE MAN TO DIG OUT A COMPLETE CEMENT JOINT, WITHOUT REMOVING THE FITTING OR GATES FROM THE LINE.

20	3	0.80	4	11
24	3	0.95	3	7

* Including the 20% of cement wasted or left over.

The writer has never cut out a joint on a main of greater diameter than 16 in. It is fair to assume that to cut out the upper half of a joint, for the purpose of removing a pipe, would take only one-half the time indicated in Table 1.

At Long Beach unit costs have been kept on all construction, covering nearly the entire 60 miles of cast-iron water mains. Table 2 has been carefully compiled from these unit costs, and presents data concerning cement joints.

DISCUSSION

Mr. Carson.

HARRY Y. CARSON,* JUN. AM. SOC. C. E.† (by letter).—It would be a valuable addition to engineering literature if some one were to compile a comprehensive and authoritative paper or thesis on joints for cast-iron pipe. Much has appeared in the technical press, as well as before technical societies, with reference to the leakage of water and gas from underground mains, but, obviously, not enough has yet been done to bring about a general improvement in the prevention of these large percentages of wasted water and gas. This paper is a valuable contribution to such literature as now exists.

The causes for the normal leakage at joints in mains may be classified as follows:

1.—Contraction and expansion;
2.—Unequal settlement;
3.—Vibration and shock.

A fourth cause may be corrosion, but a very able paper, entitled "External Corrosion of Cast-Iron Pipe",‡ by Marshall R. Pugh, M. Am. Soc. C. E., points out that deterioration in cast-iron pipe, as compared to other materials, is practically nil; that the oldest cast-iron pipe, flanged, and in 1-m. lengths, put into service more than 250 years ago, has shown no appreciable loss in wall thickness or strength, and that: "experience has not been sufficiently long to establish just what its life is." The chief consideration for cast-iron pipe, therefore, may be said to center about the type of joint best suited to prevent waste through leakage.

Contraction and expansion exist in all mains, and vary in direct proportion to changes in the temperature of the pipe line. The movement caused thereby, though slight, and scarcely ever exceeding 2 in. per 1 000 ft., is absolutely irresistible, and its effect must be taken care of properly, or disaster is sure to result. No material is of sufficient strength to resist its power if rigidly maintained against it. Contraction and expansion produce by far the greatest proportion of normal leakage in mains. Because of its inelasticity and fragility, cement, as a material for jointing cast-iron pipe, has always been questioned, in spite of the fact that it is very cheap.

The author makes the following statement:

"Long Beach now has 60 miles of cast-iron water mains, * * * laid with joints of this [cement] type. All these pipes are under pressures ranging from 40 to 80 lb. per sq. in., and are giving perfect satisfaction."

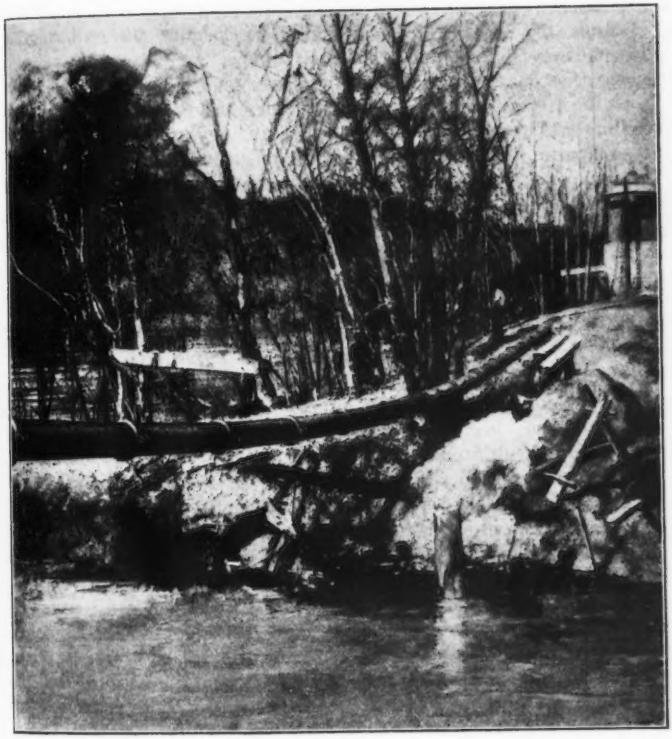

FIG. 10.—SUSPENDED LINE OF PIPES WITH METAL-TO-METAL JOINTS.

Mr. Carson.

He presents no data, however, by which the satisfactory performance of the line may be measured, as he has not submitted any information as to tests made for leakage or figures as to its quantity. Manifestly, without this information it is difficult to see how the line can be stated to be perfectly satisfactory.

The principal advantage of bell and spigot pipe when packed with lead lies in its ability to take care of the always existent contraction and expansion at its joints, without fracture. Cement joints may reduce the number of joints actually leaking, but rigidity is increased to such an extent that there may result an increasing number of fractures at those points. The net leakage with cement joints, however, is probably not materially different from lead.

Flanged jointed pipe, in order to withstand expansion and contraction, must have expansion joints at very frequent intervals.

Regardless of the kind of jointing material used, the unequal settlement of a pipe line may cause normal leakage as well as breakage, with extraordinary leakage. Damage ensues from settlement almost in direct proportion to the relative rigidity of the joint. Flanged pipe is particularly unsuited to conditions where unequal settlement prevails, as is the case in the down-town or business districts of cities, where the streets are so frequently torn up.

Vibration and shock are exceedingly deleterious to joints which are rigid, and here again the pipe line suffers in direct proportion to its rigidity. The general results are similar to those caused by unequal settlement. Moreover, main leakage will increase as the system gets older, on account of the loosening of the joints, through contraction and expansion, settlement, and vibration.

A pipe joint in which packing materials of every character are entirely eliminated, so as to have a ground metal-to-metal connection, should give the most desirable results of all. Joints of this construction have now been in successful service for more than 15 years; and their more general adoption will proceed from the excellent results which have been obtained from their use for cast-iron mains. In joints of this type the bell and spigot ends of the pipe are machined at slightly different tapers, so that, when entered in a tight manner, the line may settle without leakage. Such a pipe line is capable of taking a rough contour over the trench bottom, or of assuming a comparatively small radius on any change of alignment.

Without the slightest leak whatever, pipe and fittings made with the machine flexible joints have been used successfully to convey hot water and fluids, such as steam, where the maximum expansion and contraction would be expected.

Furthermore, cast-iron pipe in which all jointing material is eliminated gives an ideal line. It cannot fail by subsequent deterioration of the joining material. For instance, there are many alkaline

Mr. Carson.

soils* where cement is quickly attacked by chemical action, which, however, does not corrode the pipe itself.† Moreover, such materials as lead, oakum, and cement, by virtue of their resistance to stray electric currents, are known to increase the damage to cast-iron mains, that sometimes follows the improper return of electric currents from trolley car systems.

In so far as settlement and vibration or shock become effective factors in causing leakage from cement and lead joints, or from flanged joints due to breakage in the latter, no leakage has resulted from proper metal-to-metal joints, and records have repeatedly shown that such joints have withstood successfully and without failure the most severe conditions known in practice.

Fig. 10 illustrates in a striking manner the efficiency of joints of this type. The photograph from which this half tone was made was taken in April, 1914, and shows a line that was laid across the top of a dam at the plant of the Semet-Solvay Company, at Holt, Ala. The dam was washed out by a freshet. The pipe settled as shown in the photograph, but all joints remained intact. The pipe line continued to give uninterrupted service while the dam was being rebuilt, supplying water at a pressure of about 50 lb. per sq. in. The sixteen lengths of pipe affected, of which twelve lengths were entirely without support, showed a maximum settlement or deflection of 46 in. at the center of the line.

Mr. Randlett.

F. M. RANDLETT,‡ ASSOC. M. AM. SOC. C. E.§ (by letter).—This paper is of added interest to the writer, as the Water Department of Portland, Ore., has been experimenting with cement joints for the past year.

During 1916, there were laid 1 910 ft. of 8-in. and 362 ft. of 12-in. cast-iron pipe with cement joints, with the most satisfactory results.

For the purpose of investigation, and to illustrate the manner of using the materials, three lines of 8-in. cast-iron pipe were laid, according to the specifications of the New England Water Works Association, as follows:

Line No. 1. Neat cement joints; 3.5 lb. per joint; some waste; cement joint about 3 in. deep.

Line No. 2. Pig lead joints, caulked; 13.5 lb. per joint; 2 in. of lead.

Line No. 3. Leadite joints; 4 lb. per joint; 2 in. of leadite.

Each line consisted of eight full lengths, with the four center lengths arranged so that their supports could be removed.

* Investigations by Bureau of Standards, U. S. Dept. of Commerce (*Metal Worker*, October 6th, 1916, p. 136).

† *Technologic Paper No. 25*, Bureau of Standards, U. S. Dept. of Commerce.

‡ Portland, Ore.

§ Now M. Am. Soc. C. E.

Mr. Randlett.

All were laid approximately level, and were plugged and subjected to 85 lb. internal water pressure continuously after completing and setting the joints.

The two end lengths of each line were braced securely, and were supported and weighted down with fifteen lengths of 8-in. cast-iron pipe laid across the three lines on each end.

Batter boards were set up over each of the five joints, and a center-punch mark was put on the pipe under the center line mark for each line on the batter boards. A flat space was filed on each length before being center-punched, and all measurements were taken later between the pipe and the batter boards at these points.

Several observations were taken from time to time, but Tables 3 and 4 show the results of the tests as completed. Line No. 1 was loaded with 200 lb., placed at the center of each length after the supports were removed.

Line No. 2 developed leaks at once, but not until one or two of the joints had pulled out considerably were they in such a condition that recaulking would not have been sufficient to stop the leaking entirely.

Line No. 3 developed leaks at several joints, varying from a fine stream to a slow drip. All these leaks had practically stopped at the time of the last observation.

TABLE 3.

Pipe.	Line No. 1.		Line No. 2.		Line No. 3.		Remarks.
	No.	Weight, in pounds.	No.	Weight, in pounds.	No.	Weight, in pounds.

h	2892	566	2220	570	1753	581	
Averages	.....	567.5	.....	564.25	.....	573.625	

Line No. 1 has developed absolutely no leaks, even under the additional load of 200 lb. per length. Lack of time has prevented loading and observing the effect of such loading to destruction of the pipe or joint. This will be done later.

Fig. 11 shows how the three mains were laid. The letters refer to the length of pipe under which they appear. The punch marks were

Mr. Randlett.

lettered according to the length of pipe on which they occur, and the joints were lettered according to the length of pipe containing the punch mark. The longitudinal distance was measured from punch mark to punch mark.

Supports removed after first observation.

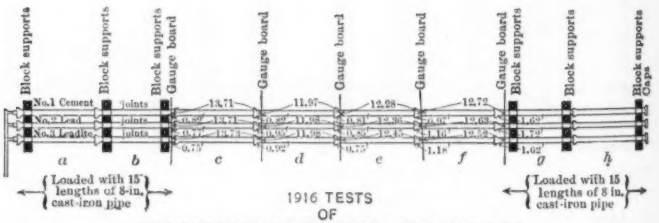

FIG. 11.

The cost per pound of the joint material was: Hemp, $0.03; lead, $0.09; leadite, $0.12; cement, $0.0055.

Mr. Randlett.

The cost per joint for material was about as follows:

Line No. 1:	Hemp,	0.20 lb. at	$0.003	$0.006	
	Cement,	3.5 " "	0.0055	0.01925	
					$0.02525
Line No. 2:	Hemp,	0.45 lb. at	$0.03	$0.0135	
	Leadite,	4.00 " "	0.12	0.48	
					0.4935
Line No. 3:	Hemp,	0.45 lb. at	$0.03	$0.0135	
	Lead,	13.00 " "	0.09	1.1799	
					1.1934

The average weight per foot of the 12-ft. lengths of pipe, including the bells, was:

Line No. 1: 567.5 lb. per length = 47.25 lb. per ft.
Line No. 2: 564.25 " " " = 47.0 " " "
Line No. 3: 573.625 " " " = 47.75 " " "

The actual weight of pipe suspended was:

Line No. 1: 2 288 + 800 (sand) = 3 088 lb.
Line No. 2:.....2 326 "
Line No. 3:.....2 311 "

In the case of Line No. 1, this would indicate, with the superimposed load of 200 lb. per length, an extreme fiber stress of about 9 000 lb. per sq. in. This may be within the elastic limit of cast iron, which varies from 6 000 to 20 000 lb. per sq. in.

Conclusions.—The conclusions from these experiments are that, for all ordinary mains, cement joints are superior to either lead or leadite; that leadite may often be used to advantage when time for setting of cement is not allowable; and that there are conditions where a lead joint might pull or blow out without breaking the pipe, and could be re-caulked and the main put in service more quickly than if cement were used.

The cost of making up joints is apparently in favor of leadite, with the cement joint next, and the lead joint the highest.

Mr. Shaw's statements in regard to the mixture of water and cement are substantiated by the work of Portland, except that the addition of from 15 to 20% of fine sand facilitates the ramming of the joint, and apparently does not materially weaken it. In dry weather it is necessary to keep the joint wet outside and inside, if possible, from 24 to 48 hours. If the joint is allowed to dry while setting, during the first few hours, shrinkage takes place, and this may or may not be taken up under pressure.

It is the custom of the Portland Water Department to test all lines to 50 lb. in excess of the normal pressure before putting the

Mr. Randlett.

line in service, and it may be said, for the cement joints and workmanship, that only one of those made in 1916 leaked under test.

The City of Portland has about 6 miles of 8 and 12-in. cast-iron pipe laid with leadite joints since 1912, and no leaks have ever been reported. Many of the joints sweat slightly when the pressure is first turned on, but they take up rapidly and become absolutely tight in a few days.

Most of the objection to the use of cement and leadite comes from workmen who have long been accustomed to the use of lead, but the writer has not heard of any complaint from engineers or foremen who have given either a fair trial. The Portland Water Department contemplates a very general use of cement joints in future work.

It is hoped Mr. Shaw's paper will bring out additional facts and opinions on this subject.

Mr. Pearl.

WALTER PEARL,* M. AM. SOC. C. E. (by letter).—In these days of Twentieth Century progress, and under the present duress of military requirements concerning our minerals and metals, this paper presents much matter for interesting discussion, in the way of economy, along the line of public work, as the latter must be continuous, and extend indefinitely, as long as civilization exists, regardless of whether the world is at peace or only striving for peace.

During several years of hydraulic engineering practice, embracing water-works construction for municipalities, the writer has noted the rapid exchange or substitution of the baser materials, metals, or elements, for those of refined, or combination metals and construction materials; in the case of wood, timber, and lumber, more metal is being used in the constructive combination.

Recently, bids were received in the State of Washington for a steel highway bridge, but as it was afterward found that a concrete bridge would cost only a trifle more, a bid was accepted for work of this class, considering the small margin in favor of the permanence of a concrete structure. There have been many similar instances lately, and as all branches of the Government and all individuals must now practice economy, this paper offers suggestions along many lines.

The method of making the cement joints, is described very clearly and concisely, including the method of breaking or loosening them, all of which would necessitate less time and expense, apparently, than is ordinarily required in melting, pouring, and driving lead joints, after caulking the joint with oakum or hemp in the usual manner, or the necessary expense and labor of melting the lead from the joints in disconnecting them; these elements of time and labor are favorable to the cement joint. However, more data and experience with

* Los Angeles, Cal.

the cement joint should be available before final conclusions can be reached regarding the relative cost of the two kinds of joints; former data cannot be used at the present time in making up a table showing the cost of lead joints. Mr. Pearl.

It is a question with the writer whether the cement, as described, is sufficiently wet to fill all the joint space, and, certainly, great care must be taken in driving or caulking the cement, as the joint space is limited, and irregularities in the pipe often provide very small space, even for hot lead.

Table 5, showing the joint space, etc., in cast-iron pipes, is taken from the catalogue of a manufacturer of cast-iron pipes.

TABLE 5.—SOME DIMENSIONS OF CAST-IRON WATER PIPE.

(Thickness of shell proportioned for 100 lb. static pressure.)

Diameter, in inches.	Length, over all.	Thickness of shell, in inches.	Depth of hub, in inches.	Joint room, in inches.
4	12 ft. 4 in.	7/16	3	5/16
6	12 " 4 "	1/2	3	5/16
8	12 " 4 "	17/32	3	5/16
10	12 " 6 "	19/32	3	5/16
12	12 " 6 "	5/8	3 1/4	5/16
14	12 " 5 "	11/16	3 1/4	5/16
16	12 " 5 "	3/4	3 1/2	3/8
18	12 " 5 "	25/32	3 1/2	3/8
20	12 " 5 "	27/32	3 1/2	3/8
24	12 " 5 "	15/16	3 3/4	3/8

The figures in Table 5 may be assumed as standard, but as the flask, mould, and pattern vary slightly with different manufacturers, the "joint room" may suffer. Table 5 shows what a limited space there is in the hub or bell for cement after the spigot end is entered, for a thickness of not less than $\frac{1}{4}$ to $\frac{1}{2}$ in. of cement should be required throughout the entire joint. This thickness might prevent the possibilities of seepage or leaks in the joints of the pipe constructed under the author's supervision. The paper gives no information regarding the joint space. In laying a line of pipe such as described, great care would be necessary in securing, as nearly as possible, perfect alignment and grade, in order to have uniform joint space.

It would seem that cement joints could only be used with straight lines of pipe under low pressures. In a joint of a 6-in. cast-iron pipe, when laid straight, the space is $\frac{5}{16}$ in., and on a curve of 250 ft. radius, the resulting space would be practically $\frac{3}{16}$ in., or $\frac{1}{8}$ in. on a curve of 166 ft. radius. Numerous ups and downs in grade could not be permitted, thus showing the necessity of laying such pipe according to the method of laying sewer pipe. This matter of joint space has been gone into at some length by the writer, as he realizes

Mr. Pearl.

the difficulty of pouring the lead in a close joint, and more especially in caulking it.

Another question arises, as to whether cement joints in a cast-iron main will stand the strain and shocks due to the sudden closing of valves and hydrants (though not necessary, such things sometimes happen), causing water-hammer, ram, and vibration in the line of pipe, which might crack or injure the cement joints, causing leakage, expense, and annoyance. This is likely to occur in a gravity pipe line, and, in a pumping line, the constant vibration might cause seepage and leaks to develop in the cement in due time. It is well known that cement and concrete will crack and disintegrate where there are sudden shocks or continuous vibration, though it will stand great pressures due to head or weight, if not subject to disturbance.

The author has described cases where pipes with cement joints were laid in made or filled ground, and where settlement occurred without injuring the joints or causing leakage; also where a parallel trench caused the caving of the pipe trench, leaving the pipe hanging unsupported in the air for a time, without even causing seepage in any of the joints. The reason for this, doubtless, was the gradual giving way of the ground supporting the main. Had the shock been sudden, the results might have been different.

It may be conceded that no other base metal having the qualities of lead—so ductile and homogeneous—seems to be as well adapted for the joints of cast-iron pipe under pressure. Lead joints may be driven or re-caulked, and all leakage stopped, while the pressure is on, which is quite an advantage over cement, as it would be impossible, practically, to secure any bond with the cement after it had thoroughly set. In case of an important leak it would be necessary to shut off all pressure on the main, and possibly the water would have to be drawn off; then, after removing all the original cement, an entire new joint would have to be made.

In a grade-line pipe, there is no doubt that cement joints would be safe and economical; but in a high-pressure cast-iron main, it would appear to the writer to be difficult to find a substitute for lead joints; under the present, prevailing high prices of materials, and especially metals, the cost and the special requirements relative to the safety of the structure, should be well considered before work begins.

It is possible that this paper may bring out some discussion relative to the likelihood of electrolysis along a cast-iron main with cement joints paralleling electric car lines; it would seem that, as cement is a non-conductor, such a line of pipe would be unfavorable to electrolytic action, as the current being so frequently broken would leave

the main in minor quantities without causing deterioration; however, experiments would demonstrate this matter more satisfactorily. Mr. Pearl.

The author states that the cement joint for cast-iron pipe has passed the experimental stage, especially in work with which he has been connected, and that such joints are safe and satisfactory. The work seems novel to the writer, and he is indebted to the author for attracting his attention to new construction methods.

H. G. MOULTON,* M. AM. SOC. C. E.—With respect to the use of Portland cement instead of lead in forming joints for cast-iron water mains, it may be said that this is the method against which there is every theoretical objection, but in favor of which there is the practical argument that it has become a demonstrated success in actual practice. For a number of years past the use of cement for this purpose has been standard practice in Los Angeles, a thriving municipality of some 350 000 population, and the speaker is indebted to William Mulholland, M. Am. Soc. C. E., Chief Engineer of the Bureau of Water Works and Supply of that city, for much interesting information in regard to this method of making joints. The following statements in regard to costs and conditions in Los Angeles are in a large measure based on figures furnished by Mr. Mulholland. Mr. Moulton.

The advantage in favor of this method lies in its great economy. In 1912 about 9 000 ft. of 30-in. high-pressure water main were laid in Los Angeles. Cement at that time was quoted at $2.00 per bbl. there and lead cost 5 cents per lb. The total saving on the job by using cement instead of lead was approximately $3 500. At present comparative prices of lead, cement, and labor, the saving would be very much greater, and, of course, on 36 or 48-in. mains a very large saving is possible.

An additional advantage in the use of cement lies in its insulating effect, in that it appears to act as a perfect seal between the separate sections of pipe and thus to reduce materially the effect of electrolysis. As damage to cast-iron pipe from stray electric currents has resulted in deterioration of water mains in many places, any type of joint which tends to reduce such damage, by stopping the flow of stray currents along the pipe, is worthy of serious consideration.

The arguments against the use of the cement joint are based on a fear that temperature changes, resulting in uneven expansion and contraction, would tend to break up the joint, and also on doubt as to the action of pipe caulked by this method in the event of settlement, in filled ground or otherwise. In Los Angeles, the usual practice is to refrain from the use of cement joints where pipe must be laid on fills, probably on the assumption that, in case of settlement opening up joints, they can be re-caulked more easily if lead is used. In Long

* New York City.

Mr. Moulton.

Beach, however, as mentioned in the paper, the cement joint has been used in filled ground, and also under conditions where trenches adjacent to the pipe have allowed sections of it to sag over a length of 40 ft. in one instance; and another instance is mentioned in the paper where some 98 ft. of pipe broke away and dropped into a trench with all the joints remaining in perfect condition, except those at the actual point of rupture.

In regard to the question of the ability of pipe to span extensive distances when the supporting ground is washed away, it may be said that, in designing connections for water pipe lines, good practice does not call for laying them out as suspension bridge connections, under the assumption that the pipe should be able to hang suspended over extensive spaces without failure. Under all normal conditions, a water pipe joint need only be considered in regard to its ability to prevent the leakage of water with reasonably continuous support and with a proper depth of cover above. Its behavior under abnormal conditions, where it has to hang suspended over wash-outs or cave-ins, is a matter of interest only from a standpoint of curiosity, and one is certainly not justified in designing all pipe on the assumption that it must meet conditions such as this, and providing special connections for this purpose.

In regard to the question of temperature changes, it may be said that there is seldom a variation of more than 50° between the winter and summer temperatures in city water mains. In winter, temperatures lower than 32° Fahr. cannot exist, on account of the fact that, at this point, the water changes to ice; and above a temperature of 85°, it is certainly too hot for use as drinking water. In Los Angeles the maximum variation in temperature is from 45° Fahr. in winter to 82° in summer, or a total range of 37° Fahr. Under this range, no trouble has been experienced with cement joints from leakage introduced by temperature stresses.

This paper brings up an interesting method which was first devised in California, and the success of which has been proved there on an extensive scale. It is no longer in an experimental stage, and is worthy of serious consideration on the part of eastern municipalities. The saving in expense made possible by the substitution of cement for lead in the joints of cast-iron pipe is so great that all the larger eastern cities would be justified in commencing immediately the use of cement joints in an experimental way in outlying districts, working gradually in to more important parts of the water system as the advantages and limitations of the method are developed in each municipality.

The author is entitled to a large measure of credit for having brought thus forcibly before the Society the advantages of a pioneer engineering method having great possibilities, which the Engineering Profession as a whole has been slow to recognize and adopt.

H. B. LYNCH,* ESQ. (by letter).—This method of caulking joints in cast-iron pipe deserves a wider use, not only on account of its low cost, but because it makes a better joint, at least where no considerable movement of the pipe is expected after it is laid. Mr. Lynch.

Cement joints have been adopted as standard at Glendale, Cal., and have been used on 10 miles of cast-iron pipe laid in the past 2 years. This joint was not adopted until investigation had shown that it is being used with perfect satisfaction in various Southern California localities, and tests had been made to show its effectiveness. The results obtained at Glendale have been similar to those described in the paper. No joint yet placed has shown permanent leakage, and, in only four, has the presence of dampness been detected after the pressure was turned on. No joint has required recaulking.

The strength of this joint has been shown at Glendale by several incidents of various kinds. As a matter of fact, it is customary for the pipe crew to take the greatest liberty with the pipe after the joints are completed, as experience has shown that a joint properly made will not be started by quite severe treatment. A 3-mile pumping main of 20-in. cast-iron pipe recently completed was entirely laid up with cement, at an estimated saving of more than $3 000. On this line, when a nipple was to be caulked into a cross, it was customary for the men to stand the cross on end on the surface of the ground and set the nipple into the top bell, and caulk up on the surface. The nipple and cross, weighing 3 000 lb. were then picked up with the chain blocks and lowered into the trench, without waiting for the set to occur. No joint treated in this way showed the slightest leakage or dampness under a pressure of 90 lb. On one occasion, a 20-in. cross had caulked into it a plug, a reducer, and a 20-in. nipple, 10 ft. long. This whole assembly, weighing about 4 000 lb., was lowered into place as soon as caulked, and is at present operating under a pressure of 90 lb. per sq. in. without seepage.

This 20-in. line was connected to a 16-in. riveted steel line. For this purpose the 16-in. line was taken out of service at 8 P. M., and put back at 4.30 A. M. Joints were given 4½ hours to set. Out of eight joints thus treated, one remained damp for one day. One joint, where the 16-in. riveted line was caulked into a cast-iron bell, dripped for two days and then took up tight. This joint showed a face of about 1¼ in. between the pipe and the bell. No other joint on this job showed any initial seepage, and all are tight now.

The method of making a joint in Glendale is much the same as that described in the paper. After yarning, the joint is rammed full of slightly damp cement. Great care is taken to caulk this first ring of cement thoroughly, as this is the greatest factor in a successful joint.

* Mgr., Public Service Dept., Glendale, Cal.

Mr. Lynch. No bead is now used, as no difference in results is noted when this is omitted. After caulking, the joints are covered with earth for protection against the sun.

The tools are slightly wider than those used for caulking with lead.

In spite of the strength of the joint, its removal is surprisingly easy. At different times, 20-in. plugs have been taken out, and there has not been the slightest difficulty where the method described in the paper was used. To caulk a joint of this size the writer allows about one hour's time of one man.

Mr. Bowen. EDWARD R. BOWEN,* ASSOC. M. AM. SOC. C. E.† (by letter).—The writer has read this paper with keen interest. It gives in admirable detail the results of an extended experience in handling the cement joint in cast-iron pipe construction. The advantages of this type of joint have not been generally realized among water-works engineers. It is not only less expensive than the lead joint, but, in some ways, distinctly better.

As protection against electrolysis it is almost a perfect insulator. Tests made at the Long Beach Water Department yards showed the resistance of cement joints on an 8-in. line to be nearly 19 ohms, or more than three times the resistance of the ordinary lead joint. Because of the high resistance, under ordinary electrolytic conditions, extremely small currents could travel along the pipe line. Tests were made in Long Beach in the vicinity of an electric railway sub-station to determine the quantity of current carried by the water-pipe lines. In this particular location there were cast-iron lines with both lead and cement joints. The position of the pipe lines with respect to their susceptibility to electrolytic action was practically the same. An appreciable flow of current was discovered in the pipe lines with the lead joints, and a very much smaller flow was noted in the line with the cement joints. In the latter instance, however, the same drop in potential could be obtained by inserting the connections in the soil at the same distance apart as they were applied to the pipe lines.

In the writer's opinion, the success or failure of the cement joint depends solely on the method used in its construction. It is extremely important to have as little moisture in the cement as possible. The mixture described in the paper has proved to be entirely satisfactory, and care should be taken to avoid using more moisture than is there recommended. If more water is used the cement in setting shrinks away from the pipe, resulting in a leaky connection.

---

* Los Angeles, Cal.

† Now M. Am. Soc. C. E.

Mr. Bowen.

Tables 6 and 7 have been prepared to illustrate the relative costs of the two types of joints. Table 6 is based on the data in the paper. Table 7 is based on the cost data assembled by the Los Angeles City Water Department.

Mr. Pracy.

GEORGE W. PRACY,* ASSOC. M. AM. SOC. C. E. (by letter).—Several months ago the Spring Valley Water Company laid 4 730 ft. of 4-in., 900 ft. of 6-in., and 827 ft. of 8-in. cast-iron bell-and-spigot pipe, with cement joints.

The cement was mixed by one man who handed it around to the two or three men making the joints. No caulking was done on the

* San Francisco, Cal.

Mr. Pracy.

joints, the cement being tamped by hand with a caulking iron. After the joint was full, a bead was put on around the face of the bell. Neat cement was used. Just as little water as possible was added in mixing. When ready for use, the wet cement was still dry enough to crumble when handled. The first few joints were filled with a wet mix, with the result that, in these joints, the cement shrunk away from the iron, and all the joints had to be remade. As an experiment, one of the 8-in. joints was caulked hard, using an extra dry cement. This gave a good joint, but not better than the others, and it took twice as long to make.

Water was turned into the pipes 48 hours after the last joint was made. For the first day nearly every joint leaked. After that, they took up rapidly and, at the end of 1 week, all were tight.

The pipe was laid in five sections of about 1 300 ft. each. All but one section was tested by measuring the quantity pumped into the section during a given period. Tests were made after the pipe had been under ordinary working pressure for about 1 week to 10 days. For the first section laid, this leakage was $\frac{1}{4}$ gal. per lin. ft. of pipe joint per 24 hours. The second leaked so slowly that the leakage could not be measured. The last two sections laid were absolutely tight. The lines were pumped to pressure and left standing, in one case, for $\frac{1}{2}$ hour and in the other case for $2\frac{1}{2}$ hours, without any drop in pressure. The 6-in. pipe section could not be tested, as it was necessary to put it into use immediately.

The quantity of cement used was as follows:

No. of joints.	Size.	Quantity of cement, in pounds.
187	4-in.	
2	5-in.	750
12	8-in.	
78	6-in.	360
168	4-in.	
86	8-in.	1 715

These figures include all waste. On an average the 4-in. joints took about 4 lb., the 6-in. joints 5 lb., and the 8-in. joints from 7 to 8 lb. These figures are rough approximations, based on the theoretical quantity necessary for a joint of each size.

The fire hydrants on the line were set with lead joints, as it was feared that the vibration of the hydrants, when in use, would break the cement joints.

The lines have given entire satisfaction.

Paper No. 1430

CONSTRUCTION METHODS USED IN BUILDING THE LOWER RESERVOIR DAM OF THE BALMORHEA PROJECT*

By Vernon L. Sullivan, M. Am. Soc. C. E.

With Discussion by Vernon L. Sullivan, M. Am. Soc. C. E.

Synopsis.

The object in writing this paper is to present economical and practical methods of constructing earth dams. In many cases, where the foundations are poor and a long section is to be built, these methods may suggest a solution which will enable the construction of a dam which, otherwise, would be impracticable or expensive.

The Balmorhea Project formerly consisted of a diversion canal which distributed the water of some very large springs for irrigation purposes. As the supply was insufficient for the area desired to be irrigated, there was constructed a reinforced concrete diversion dam, 500 ft. long, across a large and wide canyon; an intake canal, 4½ miles long, with a carrying capacity of 1 000 cu. ft. per sec.; a large earth dam, 3 900 ft. long, with a maximum height of 47 ft. above the lowest point in the creek bed, and having reinforced concrete paving on the

* Presented at the meeting of May 15th, 1918.

inner slope; an outlet conduit, well, and controlling gates; and an outlet canal, 2½ miles long.

Most of the excavation for the dam was done with a drag-line dredge, and the earth embankment was put in with twenty-six dump-wagons loaded by two elevators. The principal features of interest in this work were the excavation for the cut-off or puddle trench under the dam, the methods of settling and compacting the earth embankment, and the manner of providing a more or less flexible and expansible concrete pavement on the inner slope.

A small supply ditch, about 3 miles long, was first constructed, up the creek from a point on the hill at the height of the top of the proposed dam, in order to divert and provide water for construction purposes, principally for puddling the clay cut-off or core-wall, irrigating the earth lifts, and for concrete.

The cut-off trench, along the axis of the dam, was excavated through a rocky and gravelly surface and down to the rock or clay sub-surface, running from 0 to 20 ft. deep and from 10 to 40 ft. wide. This work (Fig. 1) was practically all done with a drag-line excavator, the excavated material of the better kind being used in the lower section of the dam.

As soon as sufficient excavation had been completed, a clay dam was placed across the trench, and the latter was filled with water from the supply ditch. Then selected clay was bull-dozed into the water-filled trench, as illustrated by Fig. 2. The filling of this trench through the water—shoving it in from the end all the time—made a complete puddle of the clay without any additional mixing.

The remaining portion of the natural surface under the proposed dam was cleared and thoroughly plowed, and then the earth embankment was put in, in lifts 3 or 4 ft. thick. Each lift was then irrigated thoroughly, as illustrated by Figs. 3 and 4, by bordering, checking, and flooding with water. The water put on each lift was sufficient to cause the moisture to unite thoroughly with the moisture of the previous lift, tests being made with post-hole diggers before the next lift was put on, and, when necessary, a second flooding was made, the object being to obtain a complete and uniform settlement of the earth, in the most economical and practical manner possible. As this method of actually saturating the earth with water quickly effects a most complete settle-

ment, and has been found to produce an impervious embankment, it is particularly suited to dam construction.

The spilling point of the reservoir is at Elevation 140, the reinforced concrete paving extends to Elevation 145, and the top of the earth dam when completed will be at Elevation 147. The front or inner surface of the dam is protected from wave action and boring animals by a more or less flexible and practically impervious reinforced concrete paving, as shown by Figs. 5 and 6. A toe-wall, or foot-wall, was built along the inner toe of the dam, to provide a footing for the concrete paving. This paving was constructed in slabs, 6 ft. wide, extending from the toe-wall to within 2 ft. of the top of the dam. It is 4 in. thick at the top, or Elevation 145, and increases in thickness uniformly to 7 in. at Elevation 100. The slabs were put in alternately, with the offset or step joint, 2 in. wide, running their entire length. The entire surface was reinforced by running heavy wire netting, of about 1 ft. mesh, diagonally across the slabs, and crossing the joints at the same elevation as the step. A thin felt strip, laid over the wire and up the sides of the step joints, provided a parting point between the slabs for expansion. The wires running diagonally through this step joint will provide sufficient give and take in the 2-in. horizontal part of the step for expansion and contraction, without undue strain on the reinforcement. Thus the entire surface of the paving is completely reinforced and bound together in a manner which gives flexibility and provides for expansion.

The dam is built on the least section compatible with good engineering. The back slope is $1\frac{1}{2}:1$; the front slope is $2\frac{1}{2}:1$ from Elevation 100 to Elevation 138, and $1\frac{1}{2}:1$ from Elevation 138 to the top.

The outlet was cut through a low saddle in a string of hills surrounding the reservoir, and from it there is built a reinforced concrete conduit, with double wells, and high-pressure emergency and service gates of standard design. The section and general plan of dam, together with the paving and other details, are shown on Fig. 7.

DISCUSSION

Mr. Sullivan.

VERNON L. SULLIVAN,* M. AM. SOC. C. E. (by letter).—Since the paper was written, the Balmorhea Dam has been put to a severe test. Early in March, 1919, a hard wind swept down the draw at practically right angles to the dam, the waves hitting the dam squarely. The storm at times almost reached the proportions of a hurricane, and was so severe that men could not stand on the dam.

It had been planned, when the earth had had time to settle, to put a vertical 2-ft. coping wall, with an overlying cap, on top, to bring the concrete slab rip-rap up to the crest of the earth dam, so as to turn back any waves that might reach that height. This had not been done when the storm occurred. The water in the reservoir was at an elevation of 137.5 ft., or ½ ft. above the change in the slope from a 2½ to 1 to a 1½ to 1, and 9½ ft. below the crest of the dam.

During the storm the waves rolled up the concrete slab rip-rap to such a height that the wind would catch under them and shoot them up the slab and over the dam; many of the waves never touched the earth dam at all, the water hitting the ground on the back side of the dam below the lower toe.

This continual action for 36 hours washed down the earth at the back of the earth dam to a point where it had been settled and packed by irrigation process during construction.

On the front of the dam, the water got behind the concrete slab rip-rap and broke it down to an elevation of 137 ft., for a distance of nearly 1 000 ft., at a point where the wind and wave action was most severe. Very little damage was done below the point of the change of slope in the concrete slab rip-rap.

Two lessons were learned: First, that a concrete reinforced slab rip-rap is good protection for earth dams where the slope is 2½ to 1 or flatter; and, second, that on a concrete slab rip-rap the surface should be roughened by setting rocks in the concrete so as to project above the surface line to break up the waves.

Paper No. 1431

IMPROVING ARCH ACTION IN ARCH DAMS*

By L. R. Jorgensen, M. Am. Soc. C. E.

With Discussion by Messrs. W. P. Creager, S. H. Woodard, W. H. R. Nimmo, and L. R. Jorgensen.

Synopsis.

In this paper the reasons for arch (rib) shortening, and the resulting opening up of the contraction joints on unloaded arch dams, are first discussed.

Crown deflections, plotted from measurements taken during a series of years on an arch dam, are given and discussed. The deflection curves indicate very plainly the great influence of temperature changes on the deformation of arch dams, and therefore, also, on the stresses in the building material (concrete) used.

It is shown how the practical arch deviates from the intended or theoretical arch; and, finally, a method is outlined for pressure grouting the spaces between adjacent walls of the contraction joints along the arch, whereby a key-stone, so to speak, is inserted under pressure into each contraction crack. This grouting is intended to be done at the end of a cold season, some time after the dam has been completed, and with the reservoir empty, or as nearly empty as possible.

* Presented at the meeting of June 5th, 1918.

The grouting puts initial compression into the arch, whereby the shearing and cantilever stresses can be cut down, perhaps to half the value they otherwise would have.

The water-tightness of the structure is also improved by this grouting operation.

Introduction.

The writer has been connected with arch dam design and construction for some years, and has taken particular interest in watching the behavior of several existing dams, especially of the arch type.

The fact that arch dams, and mainly those of heavy sectional area, do not develop arch action before considerable load has been applied to them is generally known, but, to a great extent, has not been especially considered in their design.

At present, working stresses of about 25 tons per sq. ft., as used in ordinary dam practice, are sufficiently low to produce a safe structure, even in spite of the fact that the formulas used for the design do not consider everything.

It is obvious, however, that if the practical arch could be constructed in such a way as to coincide more nearly with the ideal arch—that is, one which acts as an arch from the very start, and in which the load is mainly carried by pure arch action—a still safer structure would result. Higher unit stresses than are now common could be used with safety, if arch action could be made more definite from the start. The factor of safety to be used would depend on the importance of the particular structure in each case.

The two main reasons for the phenomenon that an arch dam does not act as an arch before considerable load has been thrown on it are, as is well known: First, the shortening of the arch rib due to shrinkage; and, second, because the arch is fastened to the foundation.

The shortening of the arch rib is caused by the natural shrinkage of the concrete as it sets, the dissipation of the chemical heat, the permanent set after the reservoir has filled once, and the fact that dams are of necessity almost always built during the season of highest temperature.

This shortening of the arch rib is plainly visible on dams provided with contraction joints. With an empty reservoir, during cold weather,

these joints will have opened up from ¼ in. to perhaps as much as ⅜ in., where spaced, say, 60 ft. apart. If not provided with contraction joints, a dam of heavy cross-sectional area will undoubtedly show cracks at more or less regular intervals from 40 to 80 ft. apart. A dam of slim cross-sectional area may not always crack, as it is somewhat flexible, and the crown can often be pulled in a down-stream direction without developing excessive tension in the arch.

In cases where the contraction joints have opened up, the water level in the reservoir will have to rise a certain distance in order to throw sufficient load on the structure to force the dam, acting as a cantilever, to deflect in a down-stream direction, before the voussoirs—that is, the bodies between the contraction joints—come into contact with one another. Only from that moment does the remainder of the water load divide up between the arch, the curved beam, and the cantilever.

In the case where the arch has not cracked, although under the influence of tensile stresses, the water level in the reservoir will have to rise until this tension has been compensated for by pressing back the cantilever. The remainder of the water load is then divided up between the arch, the curved beam, and the cantilever, according to their relative capacities for sustaining load.

The fact that the arch is fastened to the foundation prevents any considerable arch action from taking place at or near the latter; this, however, is not detrimental to the safety of the structure, such as would be the shortening of the arch due to shrinkage. The load on the lower portion of the arch causes shearing stresses in the concrete next to the rock and for some distance above and below. These shearing stresses, in turn, cause an elastic deformation, of both the dam and the rock foundation, to take place in a down-stream direction, especially at the crown of the arch, where the movement in that direction is the greatest. Ordinarily, the rock bottom has a higher modulus of elasticity than the concrete; it is well supported laterally from all sides, and therefore offers greater resistance to this movement (perhaps three times) than the concrete, but there is nothing to warrant the assumption that the rock bottom is immovable, and measurements also seem to indicate that it is not, although measurements of such movements are very difficult to make correctly, as they are so small in this region.

A trial calculation will ordinarily indicate very low unit shearing stresses at the foundation, even assuming that shear alone carried all the load on, say, the lower fifth of the dam.

The unit shearing stresses, in most cases (perhaps in all cases), will be less than the unit weight multiplied by the coefficient of friction; but, in any case, the weight of the structure will exert considerable unit compression perpendicular to the horizontal plane of shear, and thereby improve the ability of the concrete to withstand shearing stresses along horizontal planes.

Deflection Curves.

The curves shown on Figs. 1 and 2 are typical for the deflection of the crown of an arch dam due to different water loads and different temperatures of the dam body. The curves are plotted from measurements taken on the Salmon Creek Dam, near Juneau, Alaska. This dam, Fig. 4, is of the constant-angle arch type, 168 ft. high, with a crest span of 550 ft.*

Fig. 3 shows the maximum cross-section at the crown. On this cross-section is indicated a number of horizontal steel rods embedded in the masonry, 20 ft. apart. These steel rods are provided with copper points on the down-stream end for weather-proofing purposes. The different readings were obtained by sighting these points through a transit and determining their position in regard to fixed bench-marks.

It is very difficult to measure the deformation close to, or at, the foundation. It is so small that a transit reading would not be accurate enough, and if a stationary measuring apparatus was arranged on the ground, down stream from the dam, it would have to be at least 50 ft. distant in order to be on ground which does not take part in any movement caused by the load on the dam. The measuring tape or rod then becomes so long that all measurements taken must be compensated for temperature changes, and even a small error in such calculations or estimates will be sufficient to make this method of doubtful value. The best thing to do seems to be to extend downward, in a uniform direction, the curve obtained from observations at higher elevations.

The measurements on the Salmon Creek Dam were commenced on October 8th, 1914, when the reservoir was filling for the first time.

* A complete description of this dam may be found in *Transactions*, Am. Soc. C. E., Vol. LXXVIII (1915), p. 702.

and the position of all the copper points on that date is taken as zero for all curves shown on Figs. 1 and 2. The actual zero will lie a little to the left; it may be some time before the water will be low enough to determine it by measurements.

The load due to the water level shown for Curve No. 1 was sufficient to keep the contraction joints (only two) closed.

There is not much that need be explained about the results of the first and second deflection measurements—those taken on October 26th, and November 24th, 1914. The water kept rising, deflecting the crown in a down-stream direction, about as might have been expected. The fourth measurement, Curve No. 4, taken on May 18th, 1915, begins to show some peculiarity about this dam, that is, the knee in the deflection curve at Elevation 1095, which is still more apparent on the three following curves. This peculiarity is caused by construction features which must be known to be appreciated.

As it was necessary to stop construction work late in the fall of 1913 at about this elevation, the zone of the dam in this vicinity was built during the coldest portion of the fall and the coldest portion of the following spring. The total shrinkage of the concrete in this zone, therefore, has been less than the average, and the arch, therefore, takes a greater proportion of the total load than it does either above or below; in fact, some load is transferred through the vertical beam (the cantilever) to this zone from both above and below. Such transference of load also takes place through the vertical beam at the crest, as shown by Curve No. 4, but this would be expected in any case.

Curve No. 5 shows considerably more excess deformation of the dam than Curve No. 4, although the water load is only slightly higher, but Curve No. 5 was plotted from measurements taken on December 2d, 1915, at a time when the days had been short and cold for some time, compared with the long, warm days around May 18th (Curve No. 4). Curve No. 5 also indicates that the outside temperature has been lower than that of the water and the dam body below the water level for some time, as the portion of the dam above the water level is forced down stream to a greater extent than the lower loaded portion as a result of the greater shortening of the arch (rib) in the upper region, produced by a lower temperature in the upper exposed portion of the dam.

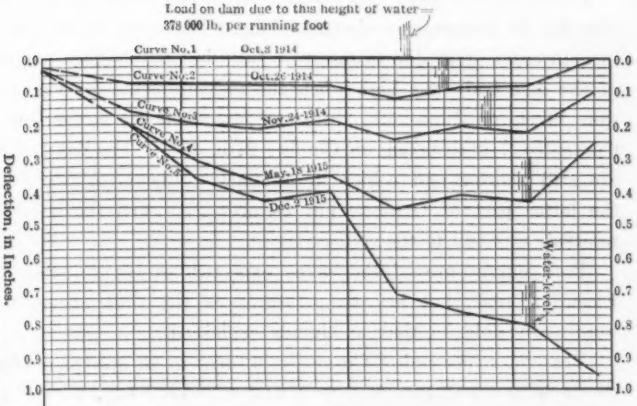

FIG. 1. DEFLECTIONS OF SALMON CREEK DAM.

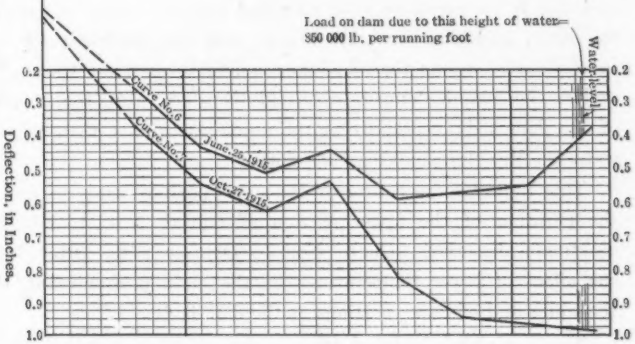

FIG. 2.

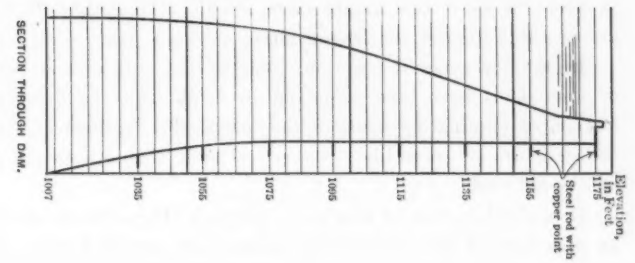

FIG. 3.

Curves Nos. 6 and 7 give an idea of the magnitude of the deformation due to temperature changes alone. The water load is the same in both cases—that due to reservoir full—but the average temperature of the dam body was high when the measurements for Curve No. 6 were taken, on June 25th, 1915, and low when the measurements for Curve No. 7 were taken, on October 27th, 1917. The days, of course, are still shorter and colder in January (Juneau, Alaska) than in the latter part of October, but October 27th was the last day the reservoir was full to the spillway crest.

Both curves are of the shape expected, except for the knee at Elevation 1095, but low temperatures at the time of construction were responsible for that, as already explained.

That the upper end of Curve No. 6 turns in an up-stream direction, the same as on Curves Nos. 2, 3, and 4, is only logical. All dams—and this is no exception—are provided with an excess of material at the crest, and therefore the stresses and the resulting deformation must be less in this than in lower zones; besides, for Curves Nos. 4 and 6, the outside temperature, and therefore, also, the temperature of the dam body, especially at the crest, was higher than that of the water on May 18th and on June 25th.

This higher temperature of the crest portion tends to accentuate the pointing of the upper portion of Curves Nos. 4 and 6 in an up-stream direction. Curve No. 7 (October 27th, 1915) indicates the effect of lower temperatures of the crest portion, than that of the water and of lower portions of the dam body.

The horizontal scale of these curves is exaggerated 1 200 times, in order to show the results more plainly. In reality, the curves are smooth, although the irregularities, as shown, are present.

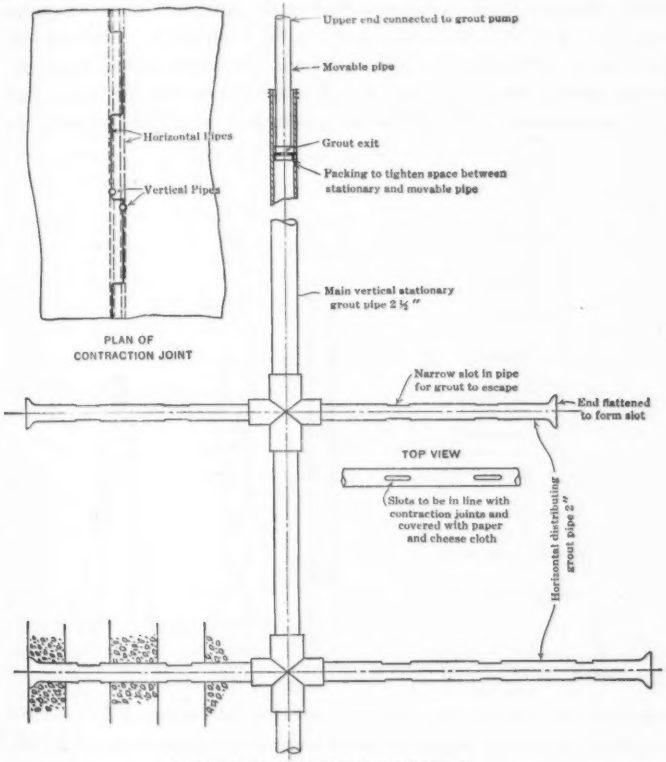
In the foregoing description, some of the actions and behaviors of arch dams have been explained in detail. In the following the method of eliminating some of the undesirable features and making the structure act more like a theoretical arch, than otherwise possible, will be outlined.

By a simple system of iron pipes (shown in Figs. 5 to 8), distributed on the face of the contraction joints, and provided with slots at certain intervals, it is possible to deliver cement grout under pressure into the space (from $\frac{1}{4}$ to $\frac{3}{8}$ in. wide) between adjacent walls of the

FIG. 4.—SALMON CREEK DAM, NEAR JUNEAU, ALASKA. 168 FEET HIGH.

contraction joints, and put initial axial compression into the whole structure, thereby making it act like a solid arch.

At the same time, this grouting will greatly improve the water-tightness of the dam.



ARRANGEMENT OF PIPES FOR GROUTING.

FIG. 5.

It is well known that contraction joints, even of the most efficient design, cannot be expected to be entirely water-tight. The leakage through such joints on large structures may easily amount to from 10 000 to 20 000 gal. daily, and has amounted to as much as 450 000 gal. daily.* This can be eliminated by grouting the joints

* *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), p. 1064.

under pressure; still, the main purpose of this grouting is to compel the arch dam to act as an arch from the very moment the water begins to fill the reservoir.

Forcing the grout into the contraction joints, and keeping it there under pressure until it has set, presses the crown of the arch in an up-stream direction, and puts shear on the foundation in the opposite direction to that due to the water load. It seems logical, therefore, to use such a grout pressure as will force the crown up stream half the total amount of the deflection resulting from a full reservoir. In

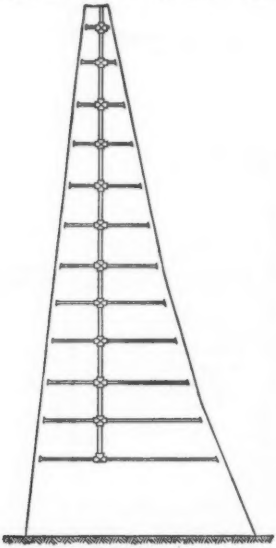


FIG. 6.

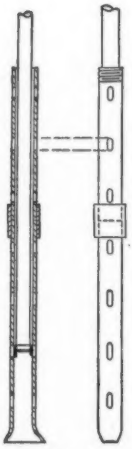

FIG. 7.

FIG. 8.

this way the maximum shearing stresses are reduced by one-half (reservoir full), the maximum cantilever stresses are reduced by one-half, and, when fully loaded, the arch compression should then be as nearly as possible in accordance with the values obtained from the simple formula:

$$\text{Unit compression} = \frac{\text{Unit water pressure} \times \text{up-stream radius}}{\text{Thickness of section}}$$

A check on the necessary grout pressure can be obtained by sighting across the crown of the arch with a transit, after first establishing the necessary bench-marks.

Great refinement in choice of final grout pressure, however, cannot be counted on, and is not essential. Considering the great influence of the temperature on the total deflection of the arch structure, as can be seen from the curves, especially Curves Nos. 6 and 7, it is necessary to use some judgment as to what the grout pressure should be in each case.

As a general rule, it can be stated that the grouting ought to be accomplished at a time when the structure is cold, and when the joints, therefore, have opened to their maximum extent, permitting easy access for the flow to all parts of thin grout (1 cement to 7 water to start with and thicker to finish). A large dam will generally have the least volume during March, and, therefore, the contraction joints will have opened up a maximum during this time, if the reservoir is empty.

When applying the grout pressure at such a time, it should be kept in mind that the dam body is larger at any other time, due to an increase in temperature, and that, with the cracks closed, the compression per square inch of contact surface will be increased as the temperature of the dam body increases.

Thus far only arch dams have been mentioned, but it would not require much explanation to show the advantage of tight grouted contraction joints on straight gravity dams also.

Grouting the contraction joints under pressure on straight dams throws longitudinal compression on the structure, and enables it to act as a beam held at both ends, at least until the initial compression has been overcome by the beam tension. A trial calculation will prove that the factor of safety has been greatly improved, especially at the lower levels, unless the dam is very long.

The grouting of the joints naturally improves the water-tightness of the dam, and, for this benefit alone, it is worth its cost. Judging from the results of analysis of leakage water through concrete dams, there are good reasons for assuming that a tight dam is going to remain safe for a longer time than a leaky one, although the writer is not attempting to predict the probable natural life of any dam.

A straight dam which has its contraction joints grouted under pressure during the cold season, will automatically have this pressure increased during the warm season, at the rate of about 11 lb. per sq. in. for each degree of rise of temperature of the concrete of 1°

Fahr., as this material tries to expand and cannot. This, of course, should be allowed for, when selecting the grouting pressure for a straight dam. There could be no objection, however, to having a longitudinal compression of, say, from 200 to 300 lb. per sq. in., or even more, on the concrete during the warm season.

A typical grout piping arrangement for a rather large dam section is shown by Figs. 5 and 6.

On the plan of the contraction joint on Fig. 5 there are two vertical feed pipes which are desirable on a joint of the kind shown. Each vertical pipe feeds a system of horizontal pipes arranged at different levels. These horizontal pipes are provided with slots wherever they cross the open space of a joint (Fig. 5). When the pipes are put in place, these slots are covered with paper and cheesecloth to prevent the concrete from entering the pipes from the outside and blocking them. Later, when the contraction joints open, this covering will either adhere to the concrete, or the grout pressure will burst it open.

The pipes cannot be recovered, but will remain forever buried in the dam. They are necessary, however, in order to keep the grout in a liquid condition from the time it leaves the pump until it passes through a slot very close to the desired point of deposit. The iron walls of the pipes do not absorb any of the water in the grout; the absorption, however, commences as soon as the grout leaves the exit slot in the pipe and comes in contact with the concrete walls of the joint. Therefore, this outside grout sets first and shrinks, to a large extent. The grout in the pipe system, being fluid for a long time, is able to follow up the shrinkage and fill out the cavities and keep the joint under pressure until the filler has solidified, in from ½ to 1 hour or more.

To avoid air pockets as much as possible, and otherwise to insure uniform work, the grouting should proceed from the bottom up; therefore a second, and movable, pipe is inserted in the stationary vertical pipe at the time grouting is to be done, as indicated in Fig. 5.

When starting to grout, one end of this movable pipe is to be at the bottom of the vertical pipe, the upper end being connected to the grout pump by a flexible connection. Grout is forced through the movable pipe and flows through the lower Tee, the lower horizontal pipes, and the slots in them, out into the space between the walls of the contraction joints, and rises vertically.

Before grouting commences, the down-stream end of the contraction joints should be caulked (with lead wool) except for small stretches left open for exploration purposes. These are closed when the grout starts to flow out of them. The up-stream end of the contraction joints are generally provided with copper plates or other kinds of effective stops.

When the grout has reached the second story of horizontal pipes, or nearly to it, the movable pipe is raised so that the lower end is just above the Tee connection leading to those pipes. Grout is then forced into them, and, proceeding in the same manner as previously described, the crest is eventually reached. Then, finally, the pressure is kept on until the filler has thoroughly set. It is the grout pressure used on the last, or preferably on the last two joints, spaced one-third of the arch length apart, that determines the initial arch compression, and therefore on these the greatest care should be exercised.

If a dam is so large and high that it takes two or three seasons to build it, it is advisable to grout the lower third of the height at the end of the cold season, before the construction of the dam is continued; otherwise, the lateral expansion (Poisson's ratio), due to the weight of material on top, will tend to close the contraction joints. These spaces will always be narrower close to the foundation than higher up, due to shearing stresses, developed by shrinkage in the concrete close to the rock bottom, tending to prevent complete contraction.

When grouted during cold weather, an arch dam will always be under the influence of compressive stresses, and any knee in the deflection curve, due to inequalities in temperature during the construction period, will be flattened out. All told, the arch dam will act more nearly as intended, carry the load as calculated, and be more water-tight than without the grouting of the contraction joints. A straight dam will have its factor of safety increased, due to the positive beam action, and also be more water-tight.

Figs. 7 and 8 illustrate a simple arrangement of grout piping for the contraction joints of a small dam.

Fig. 9 shows what is regarded as the best arrangement of grout piping for the contraction joints of a dam of medium size (the Carroll Arch Dam). The location of these joints is indicated (not in detail, however) on this figure, which also shows the complete arch, together

with its tangent spillways. The enlarged section at Elevation 250 shows the details of a typical contraction joint. Only one vertical pipe is provided, and from this several stories of horizontal pipes reach all parts of the face of the joints.

The longitudinal faces of the individual recesses, making up the contraction joint, are to be made slightly tapering, so as to make sliding more certain. It should be kept in mind, however, that parallel faces will produce the greatest water-tightness, and, therefore, the tapering should be very slight, only enough to take care of construction irregularities.

The deflection curves of Figs. 1 and 2 were made under the direction of Mr. H. L. Wellenberg, formerly Chief Engineer of the Alaska Gastinau Mining Company, Juneau, Alaska. Measurements on other dams have been made, but those given are characteristic of the deflection of the crown of an arch dam, due to changes in load and temperature.

DISCUSSION

Mr. Creager.

W. P. CREAGER,* M. AM. SOC. C. E. (by letter).—It is very interesting to note that, of the hundreds of arch dams which have been constructed, no record of a single failure can be found. This is particularly remarkable because of the fact that less is known regarding the distribution and intensity of stresses in arch dams than in any other type of masonry dam. Perhaps this signal success with such dams can be accounted for by the remarkably large factor of safety usually adopted in the designs.

With complete information as to the distribution of stresses, as effected by a combination of water load, base shear, and expansion and contraction, the economic value of this already useful type of dam would be augmented considerably.

Although engineers may never hope to obtain perfect knowledge of the subject, the results of deflection measurements, so well described by Mr. Jorgensen, assist to a marked degree and make for economies in future designs. It is to be hoped that more data of this kind will be forthcoming.

Mr. Jorgensen's ideas regarding the desirability of initial up-stream deflection, before filling the pond, is based on sound reasoning. The greatest uncertainty regarding the distribution of stresses in arch dams is the result of the unknown effect of the so-called "cantilevering action", or horizontal shear at the base, which is caused by a down-stream deflection of the upper part of the dam relative to that of the lower part, held rigid by the foundation. An initial deflection in an up-stream direction causes a negative shear which is eliminated on loading the dam, resulting in a negligible or at least greatly reduced positive shear and a better distribution of arch stresses.

If, as is customary, the dam is constructed during the warm season, the deflection during the cold season, after loading, will be considerably more than that theoretically due to the water load alone, on account of the shrinkage of the concrete in setting, and that due to a reduction in atmospheric temperature. The writer has been considering for some time the advisability of providing contraction joints having clear openings of a foot or more. If, before the pond rises, these contraction joints are filled with concrete during the cold season, the deflection due to the setting of the concrete and a reduction in atmospheric temperature would be obviated with beneficial results.

The advantage of carrying this remedial precaution to the extent suggested by Mr. Jorgensen depends greatly on the cost and effectiveness of such work. It would be interesting to know the results of Mr. Jorgensen's experience with the method of grouting proposed, par-

* New York City.

ticularly as regards the leakage of grout from the joint. Such leakage, if excessive, would be not only costly, but would greatly disfigure the down-stream surface of the dam. Mr. Creager.

S. H. WOODARD,* M. AM. SOC. C. E. (by letter).—The author has developed a serious question to be considered in designing and building arch dams. Mr. Woodard.

The general knowledge of the fact that arch dams must shorten in length by shrinkage, both when the concrete is setting and during cold weather, and that this shortening must cause re-distribution of stresses, has been in the mind of every thoughtful designer. It has been observed that nearly all straight dams and all arch dams have developed vertical cracks in cold weather, but, so far as the writer is aware, the record of actual observed deflections of an arch dam has not been published before.

The data in the paper are very useful, and probably all will agree that some steps may well be taken to accomplish what is hoped for from the grouting scheme proposed. The writer is of the opinion that, if any perfectly reliable method of accomplishing, or nearly accomplishing, this can be devised, it may well be used in preference to the grouting scheme. It is evident that, if the construction joint is only partly filled with grout, leaving certain areas without bearings when the joint is closed under pressure, the dam will be worse off than before grouting. Unless extraordinary care is taken, it will never be known whether or not the joint has been filled uniformly with grout.

The writer believes that, in most cases, wherever feasible, it will be better practice to leave narrow gaps at, say, 50-ft. intervals, and close them with concrete placed in the early spring after the dam has stood through the winter.

This, of course, will not introduce the initial stress which is hoped for from the grouting method, but here, again, unless the initial stress is uniform, the dam is better off without than with it, and there would always be some doubt on that point.

W. H. R. NIMMO,† ASSOC. M. AM. SOC. C. E. (by letter).—The deflection curves presented by the author form a valuable contribution to the available data on arch dams, and it is to be hoped that other engineers having charge of large arch dams will make similar observations. If an analysis is made of the arch and cantilever stresses at different levels in any arched dam, the results will indicate a deflection curve of the same general shape as that of the curves obtained by the author, this being especially true of the movements of the crest. The peculiar bend in the curves at Elevation 1095 is significant, as it indicates the extent to which conditions during construction may influence the subsequent behavior of the dam. Mr. Nimmo.

* New York City.

† Hobart, Tasmania.

Mr. Nimmo.

In his discussion of the late Mr. L. A. B. Wade's paper, "Concrete and Masonry Dam-Construction in New South Wales",* Mr. De Burgh describes a concrete arch dam, 38 ft. high, built for domestic supply at Barren Jack, and the deflection curves shown in Fig. 10 are reproduced from his discussion. At the right abutment, the stress is distributed into the rock by a concrete abutment and wing-wall, but it

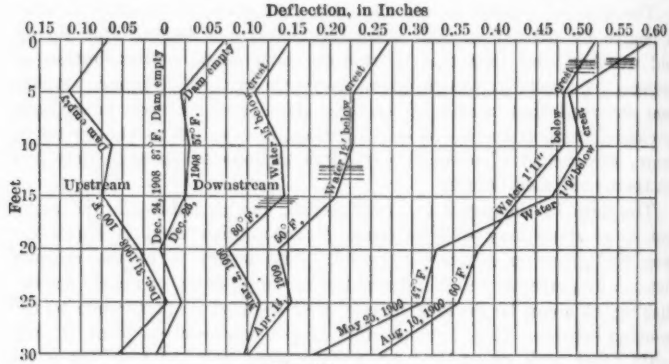

FIG. 10.

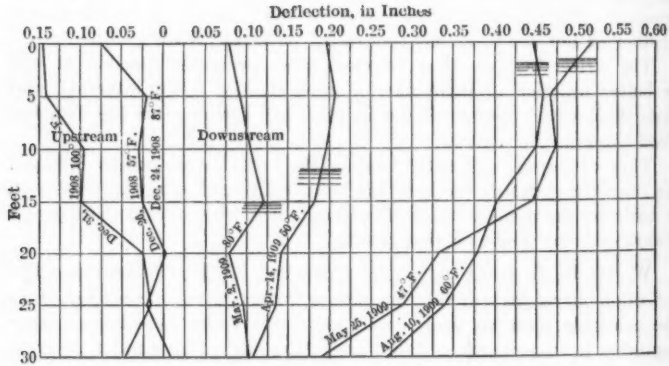

FIG. 11.

is stated that there is no indication of any yield having taken place at this point. The movements of the crest, however, are not such as theory would lead one to expect. The dam was completed in December, 1908, and the first set of measurements, used as a datum in Fig. 10, were taken on December 24th, 1908. If these measurements were taken very soon after placing the last lift of concrete, it is probable

* *Minutes of Proceedings*, Inst. C. E., Vol. CLXXVIII.

Mr. Nimmo.

that the initial shrinkage of the concrete would unduly influence the movement of the crest relative to the rest of the dam. In Fig. 11 the writer has replotted the curves, using the measurements of December 26th, 1908, as a datum, and it will be seen that the movements of the crest become more logical. The two left-hand curves of Fig. 11 show the influence of a decided rise in temperature on the thin crest (in this case 2 ft. thick). In the two right-hand curves of Fig. 11, the water is practically at the same level in each case, and, although the temperature of the air on May 25th, 1909, was below that of August 10th, 1909, the actual temperature of the water and of the thicker concrete in the lower levels would probably be higher in May than in August. The thin crest, however, would respond more readily to a fall in temperature, and this appears to be the reason for the two curves crossing each other. It is of interest to notice that the curves at a point 20 ft. below the crest show a bend somewhat similar to that shown by the author's curves at Elevation 1095, but no information is given as to temperatures during construction. This dam contained a considerable percentage of longitudinal and vertical reinforcement in the form of old rails, but its presence does not appear to have had any effect on the general shape of the deflection curves.

Mr. Jorgensen.

L. R. JORGENSEN,* M. AM. SOC. C. E. (by letter).—Both Mr. Creager and Mr. Woodard have made the suggestion that narrow gaps, say, 12 in. wide, should be left for contraction joints which should be filled during the cold season, before the pond rises.

It is true that such a wide crack could be filled more uniformly over 100% of the bearing than one only ¼ to ⅜ in. wide, but it would require twice the quantity of formwork to make this wide crack than to make the ordinary contraction joint, and the cost of this extra formwork would be considerably more than that of iron pipes for grouting purposes.

The grouting process does not take long to complete, and the richer grout will attain a high compressive strength in a short time, making it possible for the structure to withstand full water pressure very soon after grouting.

Mr. Woodard points out that, unless extraordinary care is taken, it will never be known whether or not the joint has been filled uniformly with grout. This, of course, is true.

The idea of the grout-pipe system has been developed largely from observations of how not to do grouting. The iron pipes are absolutely necessary, in order to be reasonably sure that too much area is not left without bearing.

One cannot be sure that the bearing of the contraction joint is 100%, but a water-tight joint can be obtained with less, as the voids would not necessarily connect with one another.

* San Francisco, Cal.

Mr. Jorgensen.

Arch stresses are generally kept low enough so that an accidental higher bearing stress can be taken care of with perfect safety. The material composing the ¼-in. inserted "key-stone" is well supported, and, therefore, can carry safely a higher stress than ordinary arch compression.

Mr. Nimmo's curves, shown in Fig. 11, correspond fairly well with what one would expect under the varying conditions of temperature and load.

The deflection of the crown of the Lake Spaulding Dam has been measured, from time to time, at a point 32 ft. down from the crest of the present dam (260 ft. above river level and 280 ft. above bed-rock), and at the crest.

The deformation of the concrete at the crest is more subject to variation of the temperature of the air, than at the point 32 ft. down, where the arch is thicker, which is only logical.

After the Lake Spaulding Dam was built to a height of 225 ft. above river level, in 1913, at a rather high rate of speed, the zero point for the deflection at the crest was set on November 25th, with the reservoir practically empty, but with all the chemical heat still in the concrete.

Three months later, the reservoir was full, and the cold water and air (February) had absorbed all or most of the chemical heat. The total deformation, due to the water load, the disappearance of the chemical heat, and the natural shrinkage, was 3.44 in.

The chemical heat had evidently caused the crown to be pushed in an up-stream direction about 2½ in., as the maximum deflection since has been less than 1 in. In 1916, 35 ft. were added to the top, and, at present, 15 ft. additional are being constructed.

During the last two winters, the contraction joints have been grouted with the exception of two. This grouting has had the effect of diminishing the deflection, which it should, and on July 8th, 1919, with the reservoir practically full, the point 32 ft. below the crest deflected only $\frac{3}{16}$ in. and the one at the crest only $\frac{1}{16}$ in., this latter point being more subject to the higher temperature in July.

The water load generally comes on in the spring, at the same time as the increase in temperature. When the two remaining ungrouted contraction joints are filled, it can be expected that, under the conditions stated previously, there will be no deflection, in which case the arch would act as a theoretical arch, with no secondary or cantilever stresses.

Should the reservoir happen to be full in the winter, there would still be some deflection, as then the deformation due to load would not be compensated by expansion due to increase in temperature; in fact, thermostats show a yearly variation of 20° Fahr. inside the dam, 24 ft. down from the 260-ft. crest, but the deflection would be less than if no grouting of the contraction joints had been done.

Paper No. 1432

SEWAGE AND WASTES DISPOSAL FOR THE UNITED STATES ARMY*

By Leonard S. Doten,† M. Am. Soc. C. E.

With Discussion by Messrs. Leonard Metcalf, Nicholas S. Hill, Jr., Almon L. Fales, Kenneth Allen, G. Bertram Kershaw, Edmund B. Besselievre, George T. Hammond, A. L. Sherman, J. F. Brown, Lynn E. Perry, and Leonard S. Doten.

Synopsis.

This paper presents a review of the work of the Sanitation Section of the Construction Division of the United States Army. The engineering problems are briefly discussed, and the designs of plants and equipment for the treatment of wastes and sewage in camps and cantonments of the United States Army are described. A comparison is made between the characteristics of municipal sewage and camp sewage, data being presented which show the exceptionally high concentration of camp sewage. Reference is made to special studies that were required to devise means to treat these wastes adequately.

The departure from previously recognized standard practice, in some instances, in the design of sewage treatment plants, and the reasons for it, are explained, and the results obtained at various camps are given.

Attention is called to the complexity of the sewage disposal problem, the field for careful research work in perfecting the processes

* Presented at the meeting of December 18th, 1918.

† Major, Q. M. C.; Officer in Charge of Sanitation Section, Engineering Branch, Construction Division, U. S. Army.

in use, and the necessity for the development of satisfactory plants at lower construction cost.

Although the Construction Division (Cantonment Division) of the Army was organized only a very few weeks in advance of the beginning of construction work on the great military camps and cantonments in 1917, a great deal of study, nevertheless, was given to all problems dealing with sanitation. It was recognized from the first that the correct solution of the sanitary problems was extremely important. Many references were made to the unfortunate conditions as to sanitation which obtained during the Spanish-American War. The experience gained by the War Department in establishing and maintaining camps along the Mexican Border and in Mexico was of great value in the preparation of plans for the large camps constructed during 1917. As a result of this experience, each cantonment and officers' training camp was provided with a complete system of sewerage, including modern plumbing equipment. Authorization of complete water-carriage sewerage systems for the tent camps originally constructed for the National Guard was not secured until the beginning of the season of 1918. The systems are now complete.

In sanitation, as well as in problems of structural and other branches of engineering, the engineers of the Construction Division were required to devise plans and prepare general specifications which would meet all reasonable requirements and at the same time facilitate the execution of the work as much as possible, as speed in construction was of the utmost importance.

In the preliminary work it was soon found that it would be necessary to depart quite radically from many of the recognized standards of engineering practice. This will be shown later by illustrations of designs of structures and references to specifications.

The work with which the writer has been most intimately connected consisted in the preparation of standard designs and general specifications of water-carriage sewerage systems, sewage treatment plants, incinerators, transfer stations for camp wastes, drainage and anti-mosquito work, and the design of devices for reclaiming waste products having recoverable values.

In June and July, 1917, much study was given to the problem of the collection and disposal of garbage and other wastes at the sixteen

National Army Cantonments. As a result of this, it was decided to classify the wastes and separate the waste materials in such a manner as to secure the best possible returns from their sale. This was an important conservation measure. Favorable consideration was at first given to the establishment of reduction plants for the disposal of garbage. Later, however, it was found impracticable to adopt this method of disposal, because of the abnormally high cost of equipment and the long time for delivery, resulting from war conditions.

The scheme finally adopted consisted in collecting the garbage by the duplicate can system, collecting and transporting all valuable waste materials to a central transfer station, where they were delivered to the contractor, and he was required to haul all organic waste materials to a point sufficiently beyond the limits of the Government reservation to avoid any possibility of a nuisance being created, and to protect the health of the troops. Incinerators were built at each of the transfer stations, to be used in the destruction of such waste materials as had no commercial value, and also to be used in the case of an emergency when, for any reason, the contractor failed to remove the garbage promptly.

In some instances the contractors disposed of the garbage by means of reduction plants in large near-by municipalities; and in other cases this material was fed to hogs.

The waste materials were classified as follows: Garbage, paper, bottles, tin cans, bones, fats and grease, and manure.

The sale of these materials, rather than their destruction by incineration, has resulted in a large revenue to the Government, instead of a large outlay for equipment and fuel, which would have been required for disposal by incineration. For July, August, September, and October, the sales of garbage and other wastes included in the preceding classification amounted to $360 570. At this rate, the total revenue to the Government from this source for the year would be about $1 082 000.

The conditions at military camps are especially favorable for the use of the duplicate can system of collection, as there are so many units of approximately equal population. From the sanitary standpoint this system also possesses a considerable advantage over the usual method of collection, due to the fact that the filled cans are transported directly from company kitchens to the transfer station, thus eliminating

the possibility of strewing waste materials on the grounds in the vicinity of camp buildings. The cans are thoroughly cleansed at the transfer station and are returned to the company kitchens at the time the filled cans are being collected.

The transfer stations (Plate III) are designed so as to provide the best possible facilities for the rapid transfer of wastes from Government vehicles to contractors' vehicles. Rooms are provided for the storage of non-perishable materials, such as paper, bottles, and tin cans, and a washing room is also provided for the cleansing of cans. The water for washing the cans is heated with pipe coils placed in an incinerator which is an adjunct to the transfer station.

Special designs for can-washing equipment and incinerators have been developed by the Construction Division since some of the original plants were built. The cans are placed in long vats containing hot water, in which special cleansing compounds have been dissolved, and allowed to remain a sufficient time to loosen the organic and greasy material from the surfaces. They are then taken out of the vat and placed in a small chamber, constructed of light-weight steel plates, and subjected to a strong spray of hot water, both internally and externally, which thoroughly cleanses them. The waste products resulting from this process pass through a large grease-intercepting tank before being discharged into the sewerage system.

The can-washing equipment at the transfer stations (Fig. 1), as constructed in 1917, consisted of large circular tanks for hot water only. Later, at a few plants, mechanically-operated washing equipment was provided, but more recently the type of apparatus previously described has been used as a standard at all transfer stations.

During the season of 1918, special designs were prepared for incinerators which would meet all requirements for the incineration of both animal and vegetable wastes having no commercial value.

In determining the capacity of an incinerator for a camp, it is assumed that the quantity of material to be handled would be 1 ton per 1 000 men per day, and that 8 hours would be the operating period per day.

The designs provide for ample firing and combustion chambers; a grate surface for natural draft to burn 35 lb. per sq. ft. per hour, and for forced draft, 60 lb. per sq. ft. per hour; a drying hearth to facilitate the cremation and to prevent liquids from reaching the

grates; dampers to control the draft; and ample stack area and height to prevent back-firing and produce an everage velocity of gases of approximately 20 ft. per sec. Plate IV shows a 20-ton incinerator plant.

Although provisions were made for intercepting the grease from kitchen waste-water at the time the original cantonments were constructed, it was found, later, that the commercial type of trap which had been used was not effective, owing partly to faulty design and partly to limited capacity, and, early in 1918, it became evident that a more

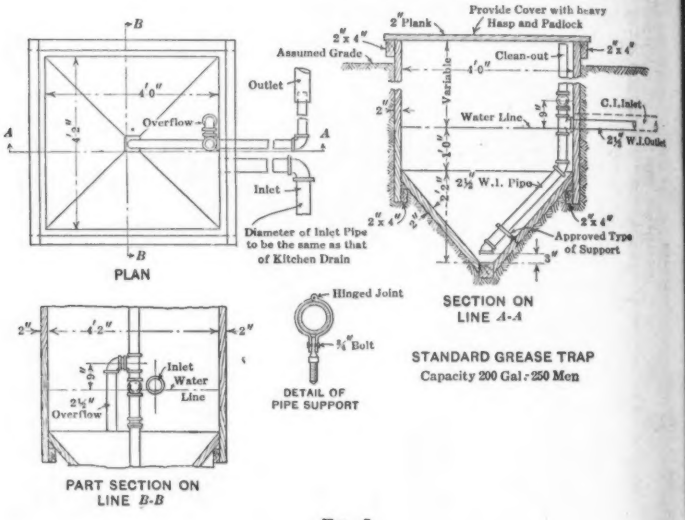

FIG. 2.

effective type should be used, in order to prevent the sewer pipe lines from being filled with grease deposits, and to relieve the excessive grease load on the sewage treatment plants. It was also recognized that the recovery of such large quantities of grease would result in a considerable revenue to the Government and would be in the interest of conservation.

Traps having a holding capacity of approximately $\frac{2}{3}$ gal. per capita were designed, and have been placed in nearly all the cantonments. (Fig. 2.) The special features of these traps are: the relatively large

PLATE IV.

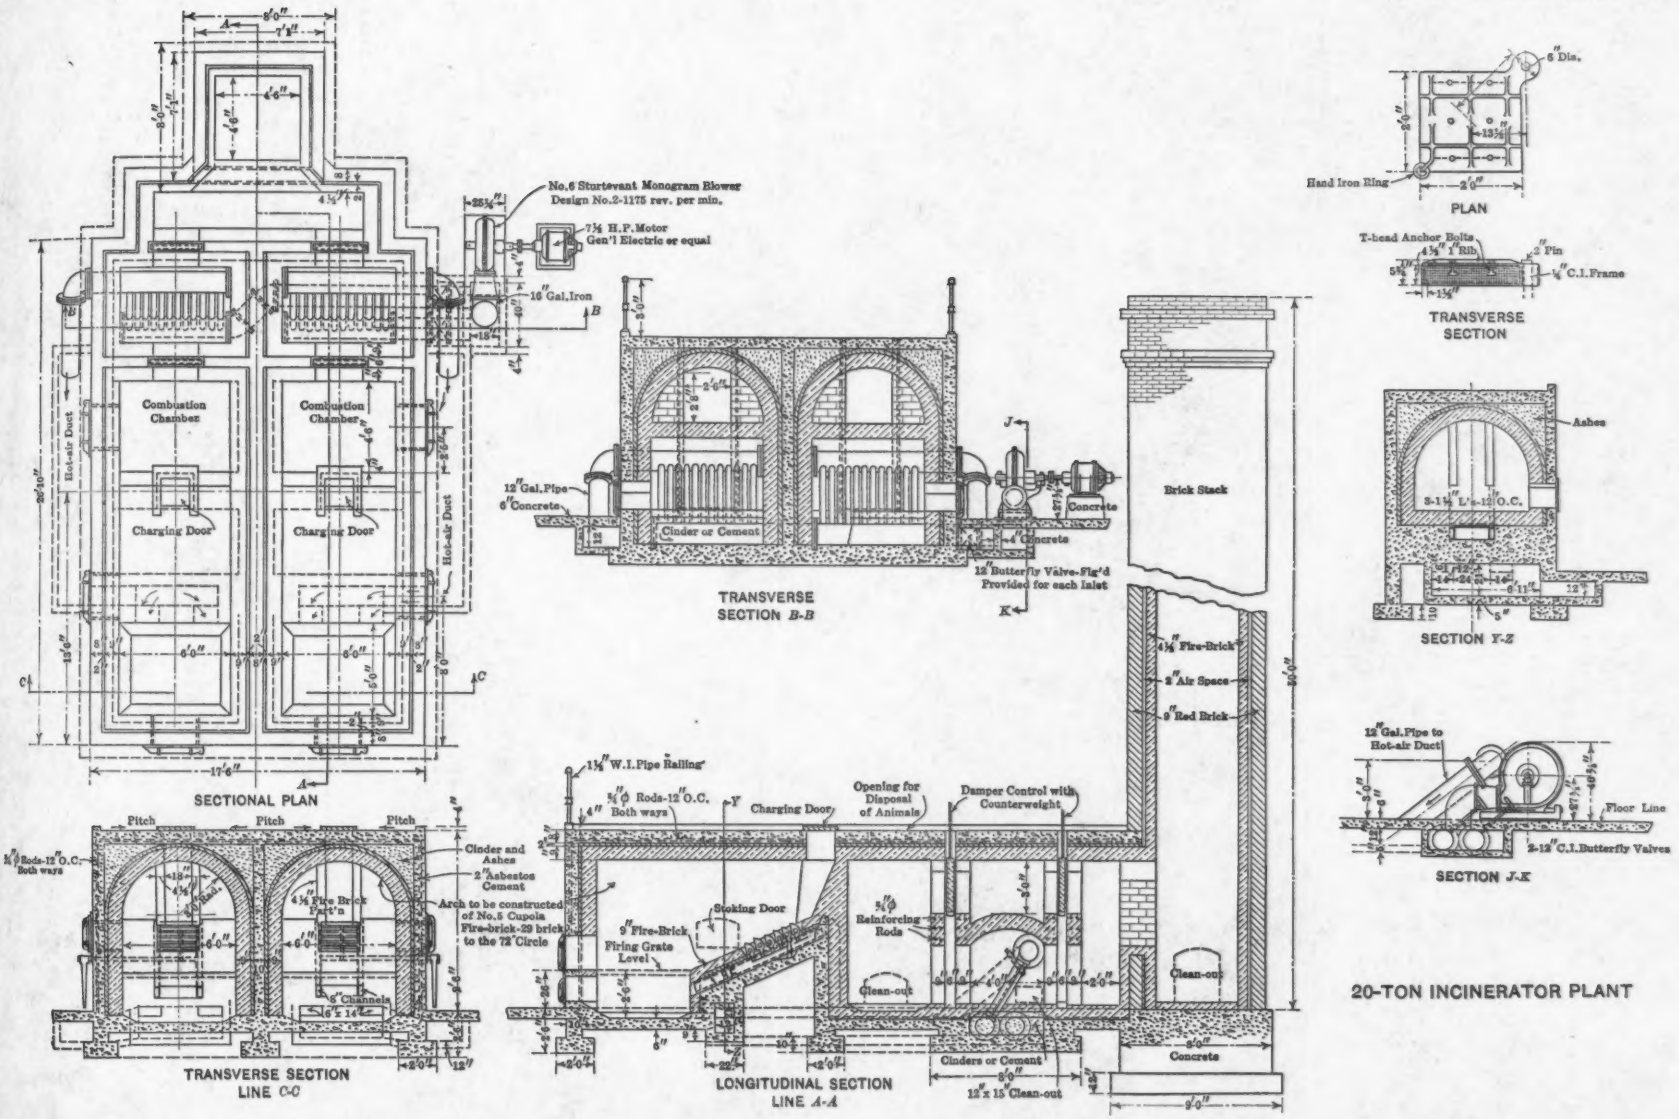
DOTEN ON
SEWAGE AND WASTES DISPOSAL.



20-TON INCINERATOR PLANT

area for the collection of grease; the steep-sided pyramidal, or conical, bottoms; and the small diameter of the eduction pipes which remove the settleable solids. The efficiency of these traps has been determined by several series of carefully made tests which show conclusively that the average efficiency under the usual operating conditions is at least 95%, and, in some instances, 99% has been recorded.

Grease recoveries by these traps range from 10 to 25 lb. per capita per year. The average is estimated to be between 12 and 14 lb. Thus, it will be seen that the revenue obtained from this waste material alone is very large at present, owing to the high prices now being paid for this product. Rendering plants have been built at some of the camps for purifying the grease obtained from the traps, in order to secure a very much higher price for the product than would be obtainable if marketed in the crude state.

Numerous determinations of the grease content of the sewage have been made at the camps, and indicate that 150 parts per million is a fair average quantity. It will be noted that this is very greatly in excess of the quantities usually found in municipal domestic sewage, the average of the latter usually ranging between 20 and 30 parts per million. This is one of the most important characteristics of military camp sewage. The following are fair averages of some of the other constituents of camp sewage:

Total organic solids.....	700	parts	per	million
Total suspended organic solids.....	464	"	"	"
Free ammonia.....	48	"	"	"
Total organic nitrogen.....	32	"	"	"

It will be seen, therefore, that the sewage is highly concentrated, and that the quantity of suspended organic matter is exceptionally high. The average quantity for nine American cities is 125 parts per million; for three English cities, 237; and for all cities, both foreign and American, it is 190. The conclusion, therefore, is that camp sewage contains about 3.7 times the average for nine American cities, 2.4 times the average for all cities, and nearly twice the average for English cities. The strength of the sewage is undoubtedly largely due to the relatively small per capita water consumption, certain waste products from kitchens, such as garbage and grease, and to the fact that the population is made up wholly of adults.

The sewage flow per capita per day ranges from approximately 35 to 60 gal. The fluctuations in the rate of flow, as shown by the graphs on the chart, Fig. 3, are much greater than in municipal systems.

When the general specifications for sewerage were prepared, it was anticipated that the maximum rate of flow from a divisional cantonment would be between $2\frac{1}{2}$ and 3 times the average rate per 24 hours. Since that time, tests on several of the systems have shown that this estimate closely approximates the actual results. The maximum rate of flow occurs during shower-bath periods, and this continues for a period ranging from 40 to 60 min. at each unit. In the original speci-

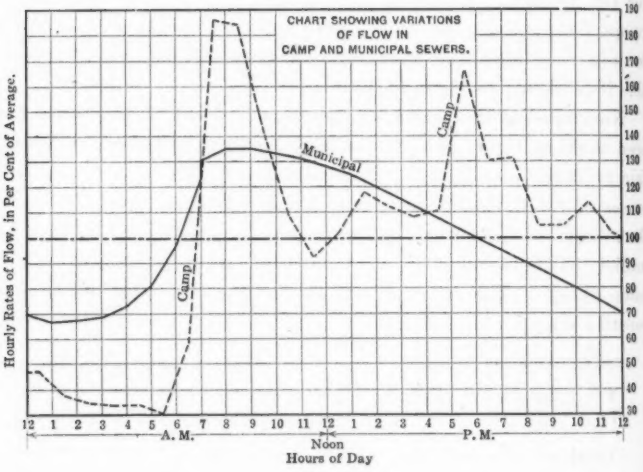


FIG. 3.

fications, certain requirements as to the capacities of the sewers were adopted. The assumption was made that it might be necessary to limit the use of shower baths in a divisional cantonment to one infantry brigade at a time, in order to avoid excessively high rates of flow, and, consequently, the construction of very large trunk and outfall sewers. As the specifications were drawn in advance of the selection of the sites for the cantonments, and, consequently, the exact location of the several units constituting a divisional cantonment had not been determined, it was impossible to calculate by a more exact method the necessary capacities of the sewer lines. Fortunately, however, the adoption of

this method resulted in a very satisfactory adjustment of sewer capacities.

As a result of the data which have since been accumulated, relative to the rates of flow in the several parts of cantonment systems, from tests made in the original sixteen cantonments, it has been possible during 1918 to check this method by a somewhat more scientific one involving as factors the maximum rates of discharge from individual units, the maximum length of time such discharges continue, and the distance that sewage would flow in that interval of time. This method of computing the sizes of sewers, in cantonments having approximately the straight-line type of layout, gives results which are materially lower than are obtained by using the former method. It is of less importance—although of considerable value—as a check on the original method in layouts approximating the horse-shoe type. In such cases, the concentration of flow at certain points is extremely high. In cantonments having a population of approximately 40 000 to 50 000, the maximum diameter for the outfall sewer is usually between 24 and 30 in.

The sewer connections to the lavatory buildings are 6 in. in diameter. In a few instances, the connections for kitchens have been 4 in. in diameter. The specifications adopted by the Construction Division contain a tabulation of minimum gradients, for sewers of different sizes, which will produce self-cleansing velocities. The calculations are based on a mean velocity of approximately 2¼ ft. per sec., with the sewer half full or full. All computations for capacities are based on sewers flowing approximately full during the highest rates of discharge.

The specifications require that the average distance between manholes shall be 350 ft. The manholes are of the simplest possible design, and are either square or round, depending on the kind of material used in construction. The sides are vertical, except where it is necessary to use standard cast-iron frames and covers. It has been the practice of the office to avoid, as far as practicable, the use of cast-iron frames and covers, both on account of the high cost of such material and the impracticability of using small covers on shallow manholes. By the adoption of wooden covers it is possible to have vertical walls, and thus improve the facilities for inspection and the introduction of sewer-cleaning apparatus. The wooden covers are very much cheaper than cast iron. A very important consideration, also, is the fact that it is necessary to lock the camp sewer manhole covers, in

order to prevent using them as receptacles for all kinds of refuse, such as old clothing, garbage, etc.

Vitrified clay sewer pipes, with the standard type of Portland cement joints, have been used almost wholly. In a few systems, concrete outfall sewer pipe lines have been constructed.

Sewage Treatment Plants.

Excepting in a few instances, where the type of sewage treatment works was pre-determined by soil characteristics or peculiarities of local practice favored by State Boards of Health, the standard type of tanks and filters adopted by the Construction Division has generally been used. Different types of tanks were very carefully considered before standards were adopted, taking into account the peculiar characteristics of the sewage, so far as known at that time, the necessity for rapid construction, and the comparative cost of different designs. The standard tanks are designed on the simplest possible lines, in order to facilitate construction and reduce the cost to a minimum. They are shown on Plate V, and are of a mutliple-compartment horizontal-flow type, provided with baffles and cross-walls, or weirs, in such a way as to facilitate sedimentation and the withdrawal of sludge. The bottoms of compartments are pyramidal.

In operation, the tanks are comparatively easy to control, especially with domestic sewage of average quality. In this respect they have a marked advantage over the older types.

Among other types considered for use at cantonments was the Imhoff tank, but the principal reasons for not adopting it were: (1) the high cost of construction, estimates showing that their average cost would be approximately three times as much as for the single-story tank; (2) the time required for construction would be at least twice as great as for the latter; and, furthermore, it would be less well adapted for treating the fresh uncomminuted camp sewage (Fig. 4). In the light of more recent developments, it is fortunate, for another reason, that the Imhoff tank was not adopted, namely, the difficulty of using a short-period, sedimentation tank which is incapable of protecting filters against excessive quantities of grease carried in the sewage.

The practice of the Construction Division has been to build treatment works only at camps where it was impracticable to construct an outfall sewer to connect with a city system, or to dispose of the sewage

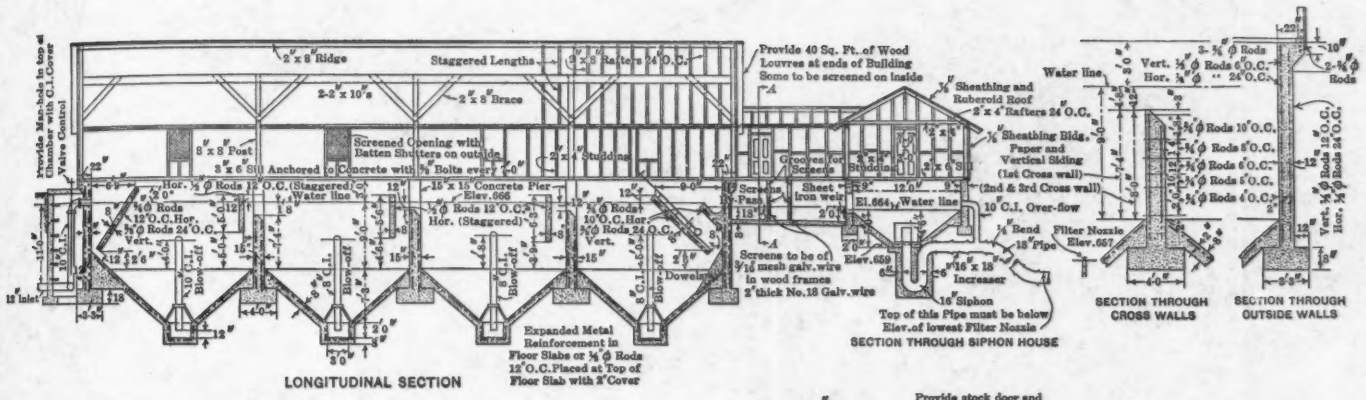
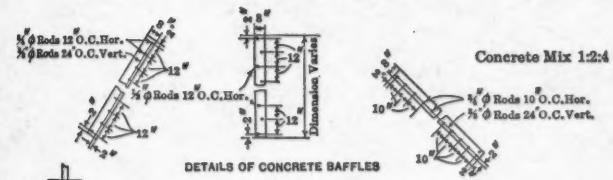
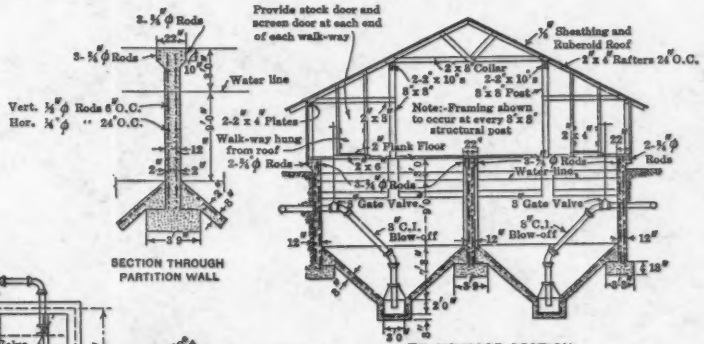
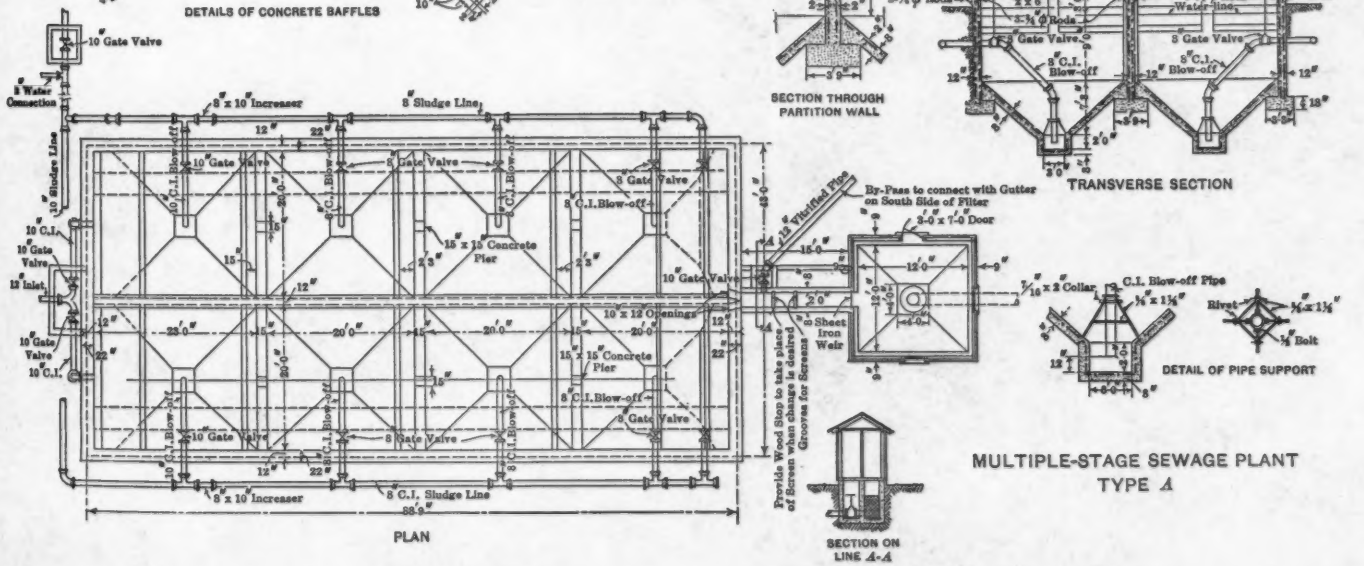
DOTEN ON
SEWAGE AND WASTES DISPOSAL.







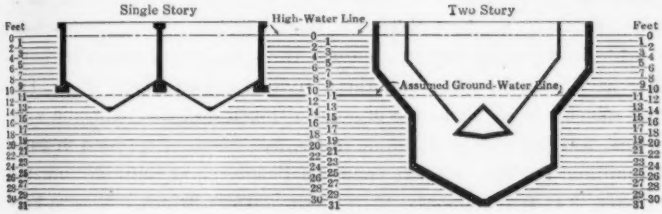


MULTIPLE-STAGE SEWAGE PLANT
TYPE A

by discharging it into a large body of water, or a river where the dilution factor would be satisfactory.

In most cases, the treatment works consist of sewage tanks and chlorinating equipment only. In comparatively few cases has it been necessary to put in secondary treatment works consisting of trickling filters and secondary sedimentation tanks.

The trickling filter, Fig. 5, owing to its large unit capacity, simplicity of operation, and low cost, was adopted as the best means for secondary treatment. The designs for these filters differ in several important details from the usual municipal engineering practice. Deep, expensive excavations were avoided wherever practicable, advantage being taken of the conformation of the site. This was also true of the retaining walls, which were omitted wherever possible, terminating the filtering material with steep slopes.



CROSS-SECTIONS OF SEWAGE TANKS OF EQUAL CAPACITY SHOWING THE RELATIVELY GREAT DEPTH OF A 2-STORY TYPE AS COMPARED TO THE STANDARD TYPE. THE COST OF THE FORMER TANK IS GREATLY INCREASED ON ACCOUNT OF DEPTH BELOW GROUND-WATER LINE.

FIG. 4.

The filter has an undulating floor, the distributor pipes being placed on the summits and pipe-covered gutters in the depressions. Thus, the expensive system of under-drains, which is usually an important feature in plants for municipalities, was eliminated. The inverts of the drains and gutters are in a plane parallel to the plane passing through the spray nozzles. This plane has an inclination approximately equal to the hydraulic gradient of the distributing system during the average rate of discharge from the nozzles.

The filtering material consists of hard, durable, crushed rock or slag, the pieces of which will pass a screen of 2½-in. openings and be retained on a screen having 1½-in. openings. Relatively coarse rock, having little variation in size of pieces, is favored, as such material has large voids, which are not completely filled with accumulations or

films, and consequently admit of a free circulation of air. The first filters constructed were 6 ft. deep. In a few plants for hospitals, 8-ft. filters were used. The present standard depth for trickling filters is 5 ft.

Dosing or Siphon Chambers.

The writer's experience and observations led him to devote a great deal of attention to the design of siphon chambers, with a view to securing the highest possible efficiency in the operation of trickling filters. A radical change has been made in the dosing period, reducing it from 4 or 5 min. to a maximum of 1½ min. for filters of all depths. Filters not more than 5 ft. in depth, when dosed in this manner, will yield a uniformly stable effluent, which is generally very low in turbidity. The degree of nitrification and oxidation which takes place in such a filter is equal to that obtained from deeper filters, as is illustrated by the following figures taken from a recent report on a series of tests on the Fort Myer, Va., filter. In this report, a comparison is made between the results obtained from the experimental trickling filter at Boston in 1907, and those from the Fort Myer filter. The tank effluent, in so far as the organic nitrogen and free ammonia were factors, was practically the same in the two cases. Expressed in parts per million, the filter effluent from the Boston plant contained organic nitrogen, 3.4; free ammonia, 12.0; nitrites, 0.8; nitrates, 5.3. The Fort Myer filter effluent contained: organic nitrogen, 0.7; free ammonia, 1.8; nitrites, 0.4; nitrates, 25.7. The Fort Myer effluent averaged in dissolved oxygen 42% of saturation. This filter, in the same series of tests, gave an average reduction of 95% in total count of bacteria and 92% reduction in *B. Coli*. Numerous tests, made during the past 8 months, on the effluent from this filter, have shown 100% stability at all times.

During the season of 1917, all sewage treatment plants were designed by the supervising engineers in the field, following the requirements of the general specifications and standards which had been adopted by the Construction Division. During the season of 1918, however, the engineering force of the Sanitation Section of the office has been largely augmented, and all designs for treatment works have been prepared in the Washington office. This has been found to be a more satisfactory arrangement than that of the previous season.

The following assumptions are made in the design of all sewage treatment plants: For temporary camps or cantonments, average daily

Fig. 5.—Sewage Disposal Plant at U. S. A. General Hospital No. 3, at Colonia, N. J.

FIG. 5.—SEWAGE DISPOSAL PLANT AT U. S. A. GENERAL HOSPITAL NO. 3, AT COLONIA, N. J.

per capita flow of sewage, 60 gal.; hospital plants, 150 gal. per bed per day, and 60 gal. per attendant per day; average detention period in tanks, 6 hours, based on net capacity of tank, making a certain allowance for sludge capacity; maximum dosing period during highest rates of flow, 1½ min.; filter capacity, 30 000 population per acre, with 5-ft. depth.

Up to the close of 1918, the Construction Division has built 150 tanks of standard design and they have a total holding capacity of 20 000 000 gal. These plants are distributed throughout all parts of the United States. Comparatively few filters have been constructed, the total number being only 19, having a total area of 447 000 sq. ft.

The writer's experience leads to certain conclusions relative to sewage treatment plants and processes, which are summarized as follows:

Sewage contains both acid and base-forming constituents. If the base-forming elements predominate, the decomposition of sludge and scum will be rapid. If, on the other hand, the acid products of decomposition are not promptly neutralized, bacterial decomposition will be greatly retarded.

If the water portion of the sewage is high in alkalinity, the bacterial action will be vigorous, and the digestive capacity of a tank correspondingly increased. Co-ordination of certain observed facts relative to the performance of tanks in widely separated parts of the country has confirmed this conclusion.

The color of sludge alone is not a true indicator of thoroughness of digestion, as the sludge in an Imhoff tank may be blackened by the presence of iron sulphide, one of the products of decomposition, and still be incompletely digested. It is true, however, that well-digested sludge is either dark brown or black. Furthermore, the so-called "tarry" odor is not an essential characteristic of thoroughly digested sludge, as the writer has examined many samples which not only did not have an odor of this kind, but were practically odorless, and dried very rapidly, even under adverse conditions.

The effluent from a Construction Division type of tank, when functioning normally, is superior to that of a plain sedimentation tank, due to the fact that the very finely divided matter borne in suspension is partly mineralized.

The capacity of a trickling filter does not vary directly with the volume of filtering material, a 5-ft. filter giving as good results as a

deeper one. The average rate of dosing for filters of all depths should not exceed 2 000 000 gal. per acre per day, if a high degree of purification is desired. The short dosing period is of more importance than perfect distribution.

The humus discharged from properly functioning trickling filters should not create an objectionable condition due to putrefaction. The putrescible character of the effluents from some deep trickling filters, and also the humus held in suspension, is due either to an inferior quality of tank effluent or to improper dosing. If the flow from spray nozzles continues too long, the entire depth of filtering material will be drenched, with the result that insufficient time will be given for the thorough oxidation and nitrification of the organic matter. The flow from under-drains should be maintained at as uniform a rate as possible.

Treatment by intermittent sand filters, even in localities where the soil is of exceptionally good quality for the purpose, has not been as satisfactory as anticipated, owing to the unusually high grease content in the sewage. It has been necessary, consequently, in certain instances, to put in tanks for the preliminary treatment of the sewage before discharging it on the sand beds. Furthermore, such plants (intermittent sand filters) are usually higher in cost of construction, and considerably more expensive to operate, than those of the standard type.

The wide variations in rates of flow at camp sewage treatment plants, the extremely high suspended organic content of the sewage, and the inhibiting influence on bacterial development resulting from the excessively large quantities of grease, are important factors in determining the load which is borne by the camp sewage tanks. Statistics fail to show that there has ever been any instance where these adverse fundamental factors were so great. This is a fact that should not be overlooked in assigning tanks of this type to their proper place in the sanitary engineering practice of the future.

It is realized that the problem of sewage disposal is very complex, due to the great variety and combinations of waste matter which constitute sewage. There is an ample field for research work along several lines, in order to perfect the processes now in use, and to develop, if possible, plants which will give satisfactory results at lower construction cost. The economic factor should not be overlooked, as it has a most direct influence in determining the progress in this field of sanitary engineering.

DISCUSSION

Mr. Metcalf.

LEONARD METCALF,* M. AM. SOC. C. E.—This paper has summed up in a very good, descriptive way the admirable work done by the Construction Division. It is to be hoped that before Maj. Doten completes his work on this subject, he will submit with his paper some of the analytical results which have been made, bearing on the operation of the plants.

In judging of the work done in this branch of the service, as in the work of actually building the cantonments, one must remember the very short time which was available, in the first instance, for building the sewerage systems, as well as the camps.

The periods for which the camps were to be operated, was a very important factor in determining the most desirable kind of disposal.

Maj. Doten perhaps has not given as clear an idea of his worries in consequence of the grease problem, because the conditions, as he has pointed them out, have been found to be quite different from those realized in many municipal plants, and have been a source of very great difficulty.

The question of how to handle the grease problem in the best way, involved the question as to whether or not it would be possible, with so many different buildings, so many different centers in the camp, to separate the grease, as was desirable, before it mingled with the fœcal matter, because the grease would obviously be much more valuable, be more salable, if the separation could be made. The way in which this problem has been worked out seems to the speaker to be good.

Final judgment on it cannot yet be passed, perhaps, but certainly the underlying principles—to have a large area for cooling the hot liquids, the tubs of dish-water that are turned into the sink, which on account of their volume and temperature tend to carry the grease forward; the small outlet, which will give scouring velocity; and sufficient slopes to enable the traps to clear themselves of solid matter—are all sound. Although some changes may be necessary perhaps, a definite step in advance seems to have been made in the matter of the economical handling of the grease problem in camps and cantonments.

There is also included in this grease problem the question of good administration. It has been felt very markedly in these cantonments, as well as in municipal plants, and is a factor which has to be kept in mind by the designing engineer when he comes to pass on the details of his plant, because it is possible in military camps to give orders and to have them enforced in a way which is not always possible in municipal plants.

The acid or alkaline character of the sewage solids in the tanks varies with the character of the water supply, and affects the sludge digestion.

* Boston, Mass.

Mr. Metcalf.

The best design for the tank which Maj. Doten has shown, and its efficiency as a digestion tank, is still open to debate and proof. It is a question on which various men who have observed these tanks, and some who have made experiments on them, perhaps differ; and for that reason it is desirable for Maj. Doten to submit the facts, as he has been able to develop them, with the greater facilities which he has had recently for following by chemical analysis in a general way the operation of these tanks.

It has seemed to the speaker, as he has visited and viewed perhaps twelve or fifteen of the camps, in the West, in the South, and around New York City, though he has not had the opportunity recently to keep closely in touch with them, that the tank was more essentially a clarification than a digestion tank, and that its most effective operation was found in its use as a sedimentation tank rather than as a digestion tank. This was anticipated in principle by some, and, it is believed, has been proved in operation.

On that question Maj. Doten may differ radically with the speaker, and that is one reason for hoping that he will give the facts, in order that the truth may be established.

In the early operation of the tanks, it is to be borne in mind that the available capacity was substantially greater than later, when the numbers of men at the camps had increased. The tanks were designed on the basis of 10 gal. per capita. On the basis of that capacity, experience seems to have demonstrated that they could not act as true digestion tanks. In other words, when the attempt was made to operate them as digestion as well as sedimentation tanks, they were soon gorged, and the accumulated solids had to be removed. Sedimentation was their best function, under those circumstances, and, if so, it is necessary to limit the accumulation of solids in the first compartment of the tank by removal of the excess of sludge and scum in order that the digestion process can go on in the other compartments. If solids are removed, as has been necessary, the question immediately arises, what is the relative percentage of the solids disposed of by digestion, on the one hand, and by sedimentation and removal in an undigested state, on the other.

The effect of the different methods of operation on the freshness or staleness of the tank effluent is also of much importance. As the process of removal is not a pleasant one, it is to be avoided as far as practicable.

Good judgment was shown in the adoption of the 10 gal. per capita basis of design, chosen as an economical procedure, for the reason that the life of the camps, and hence of the disposal works, was limited to a period of 5 years, and that it was recognized that it might not be greater than 2 years. That has proved to be the case in the majority of the camps. The lower first cost of sedimentation tanks was balanced against the lower operating expenses of digestion tanks.

Mr. Metcalf.

The speaker questions whether the form of the pyramidal bottom was worth its cost, as observed at the various camps. There is no doubt that the tank with a pyramidal bottom was materially more expensive than a rectangular tank of the same capacity. It may be questioned whether in operation it was any more economical, because the slopes are not steep enough to force the solids down. On the other hand, they are so steep as to be impossible to stand on for scraping, though they can be flushed by hose.

The speaker is very much surprised at Maj. Doten's statement in regard to the efficiency of tanks of various depths, because this appears to be out of line with the results of experiment, and of experience in municipal plants in the United States which have been operated up to this time, so far as the speaker knows them. It is to be presumed that Maj. Doten speaks with knowledge derived from his experience, and, therefore, his evidence will be awaited with interest.

In the matter of placing the sprinkler nozzles on the trickling filter beds on a slope, that is, not in the same plane, the speaker's observation has indicated it to be distinctly disadvantageous rather than advantageous, as it has resulted in overtaxing locally certain portions of the bed, and has failed to give as good distribution as under the more usual course of procedure.

In so far as municipal practice is concerned, some other types of under-drains will probably prove more advantageous than the form which has been used in these camps; nevertheless, good judgment was shown by Maj. Doten in using the simplest form, in the interest of greater economy for temporary construction. Maj. Doten's record of service is much to his credit.

Mr. Hill.

Nicholas S. Hill, Jr.,* M. Am. Soc. C. E.—Mr. Metcalf has covered some of the points which the speaker had in mind to make. He wishes, however, to emphasize the statement that these tanks are primarily clarification tanks, and not digestion tanks. From his connection with their operation, the speaker feels that a saving in first cost could have been effected, and with as satisfactory results, if their design had been simplified. He is satisfied that the division into compartments was a mistake. At Camp Merritt it was found that the major part of the sedimentation occurred in the first compartment, and that the second, third, and fourth compartments contained only a small quantity of sludge. In fact, at Camp Merritt, a by-pass was provided from the first tank, and arranged so that sludge could be transferred therefrom to the second, third, and fourth compartments. If this had not been done, the first compartment would have had to be cleaned frequently, and it would have been necessary to clean the remaining compartments at intervals, increasing in length, up to a maximum for the last compartment.

* New York City.

Mr. Hill. The speaker has serious doubts about the design of the grease traps adopted, and whether the high velocity idea is a practical one. He would not design a grease trap along the lines of the one used for the cantonments, and, from observation of the operation of these traps, he knows that there was lost from them a large quantity of grease which could have been saved with slight modifications of design.

In the camp with which the speaker had to do, difficulty was found in getting those who attended to the grease traps to remove the grease from the surface around them. The result was that with grease lying on the surface in the summer, an attractive center for flies was created, which was objectionable, particularly as the traps were near the kitchens. It is realized that it was necessary to remove the grease at the source of production, before it mingled with human wastes, if it was to be obtained in a condition ready for use, but the system of placing individual grease traps on kitchen connections in municipalities would be impracticable, for various reasons, and, if grease is to be withdrawn from the sewage, it will have to be done at the point where the sewage is treated. The speaker mentions this for fear that some one, reading of the successful operation of the grease traps in the cantonments, will seize on the idea that a large return can be secured in municipalities by adopting the same process. If individual grease traps can be adapted to municipal work, their form will certainly have to be modified materially from that used at the cantonments.

The general design for the sewerage systems for the cantonments showed much foresight on the part of those who laid them out, and the assumptions which were made were borne out in general by actual experience in the several camps. The design generally is to be commended.

In connection with the work of construction, it might be well to refer to the use of trenching machines. The conditions at Camp Merritt were such that the use of these machines was practically impossible. The contractors procured ten or twelve of them, with the idea of doing the work expeditiously, but when the trenches were opened, rock was found in some cases, and in other cases the sandy soil contained water, and where that was the case, it was found that hand labor was more economical than the trenching machine, because it was practically impossible to sheathe the trench directly behind the machine. The trench caved in, and the hand work required in removing the fallen material was almost equivalent to that which had to be done originally. A number of methods of working behind these trenching machines in wet ditches was tried without success. They may be modified so that they can be used where the trenches are wet, but, as designed to-day, they are not useful under such conditions. These machines were handicapped to such an extent in various places, on account of obstructions, that hand work had to be resorted to for a

large proportion of the work, and, at Camp Merritt, hand labor was found to be more expeditious and cheaper. Of course, where the trenches were shallow, as in the case of water mains, a small trenching machine was used to great advantage. The difficulties referred to relate more particularly to the use of these machines for sewer work. Mr. Hill.

ALMON L. FALES,* M. AM. SOC. C. E.—This paper is especially interesting to the speaker, because of his work for the Construction Division of the Army, in connection with water supply and sewage treatment at the army camps. He has inspected the sewage tanks, designed by Maj. Doten, in operation at numerous camps, and has made thorough investigation of their efficiency at several of the camps. Mr. Fales.

The efficiency of sewage tanks may be judged by three important standards:

1.—Removal of suspended solids in the sewage, which will settle to the bottom as sludge or rise to the top as scum;
2.—Digestion of the solids removed, with the production of inoffensive matter.
3.—Reduction in biochemical oxygen demand of the sewage, measured by the relative volumes of diluting water necessary to render the sewage and tank effluent non-putrefactive.

Judged by the first and third of these standards, these tanks were found to be very efficient, when the accumulation of sludge and scum was removed with sufficient frequency to avoid excessive fermentation or septic action and to prevent disgorgement of solids at times of high flow. In other words, they were efficient when operated as plain sedimentation tanks. The nature of the fresh uncomminuted camp sewage is favorable to the removal of a large proportion of the suspended solids by sedimentation and flotation.

Judged by the second standard—digestion of solids—these tanks were not efficient, with a capacity of 10 gal. per capita served, which was the basis of design; and tests at one camp indicated that complete digestion of the solids could not be secured even with a capacity as high as 35 gal. per capita. At several camps some well-digested sludge was produced in the third and fourth compartments, due, in part at least, to the mechanical separation of the less easily digested solids in the first and second compartments, but, as far as the speaker is aware, in no case was the rate of production of well-digested sludge equal to the rate of accumulation of fresh solids in the tank.

To what extent the inefficiency of the tanks in the digestion of solids was due to the large proportion of fats in the camp sewage has not been ascertained. There is no doubt that some improvement will result from placing efficient grease traps on the kitchen drains. With

* Boston, Mass.

Mr. Fales.

such traps it seems certain that satisfactory digestion of the solids can be secured, if unlimited tank area and capacity are available. The area and capacity required in the tanks to accomplish this have not been determined, but they exceed by far the basis of design.

If the tanks are made adequate for the digestion of the solids, and are operated according to the principle of the designer, the tank effluent will be charged with the gaseous and liquid products of digestion and with more or less finely-divided suspended and colloidal matter, resulting from the process of digestion. The effect of this action is to render the tanks inefficient, judged by the third standard, namely, the reduction in the biochemical oxygen demand of the sewage. At some camps, where digestion was taking place, the tank effluent was found to have a higher oxygen demand than the crude sewage itself. Such a tank effluent is likely to be malodorous and to require an abnormally large proportion of chlorine for disinfection and a relatively large volume of diluting water to render it non-putrescible. Further, it is the consensus of opinion that such a tank effluent cannot be treated by processes of bacterial oxidation—such as filtration through trickling filters—as advantageously as one which is not affected by the products of decomposition of the sewage solids.

In the speaker's opinion, to secure efficient tank treatment it is necessary to separate the functions of sedimentation and sludge digestion. This may be accomplished by the so-called two-story tank, in which the opening from the sedimentation compartment into the sludge compartment is trapped; by separate sludge digestion tanks; or by operating tank units in rotation, first for sedimentation and then for sludge digestion.

In accordance with the recommendation of the consulting engineers (Messrs. Fuller and McClintock, and Metcalf and Eddy), the number of tank units, at most of the large camps, has been, or is being, increased to at least five of 7.5 gal. per capita each, in order to permit of operation by the rotation method; and provision is made for pumping the sludge and scum from any compartment of any tank to any other compartment, in order to facilitate the digestion of the solids.

The speaker is glad to corroborate what Maj. Doten has said in regard to the character of the effluent from the sedimentation tanks at the Great Lakes Naval Station.

At the time the speaker was there, this effluent was characteristic of that from septic tanks—black and foul and heavily charged with fine suspended matter, probably to a large extent sulphide of iron. In answer to a question raised by the speaker, he was informed that it was out of the question to allow this effluent to flow down the aerating effluent flume, on account of the foul odors created.

This condition of the effluent was evidently due to the presence of decomposing sludge in the sedimentation tanks, and illustrates the

effect of attempting to secure sedimentation and sludge digestion in the same tank, at the same time. Mr. Fales.

Whether the sludge was not being drawn from the sedimentation tanks into the separate sludge digestion tanks with sufficient frequency, or whether the bottom slopes of the sedimentation tanks were not steep enough to be self-cleansing, and thereby prevent accumulations of solids in the tanks, was not ascertained.

KENNETH ALLEN,* M. AM. SOC. C. E.—It might be of interest to mention a tank devised by J. W. Alvord, M. Am. Soc. C. E., and used as a standard by the United States Housing Corporation. Mr. Allen.

The unit (Fig. 6) is supposed to serve for a 1 000-house development. It consists of a primary settling tank with three hopper bottoms 12 ft. square, sloping 60° from the horizontal, and extending about 16 or 17 ft. below the top of the tank; a secondary settling tank, similar and parallel to the one described; and, between these two, a sludge digestion tank of equal length, width, and depth, but with a single hopper.

The baffled sewage flows from the primary to the secondary tank over the sludge tank by several troughs, and the scum can be pushed along special troughs connecting each settling tank with the sludge tank.

The sludge which collects in the six hoppers of the primary and secondary tanks is drawn into the hopper of the sludge tank merely by lowering the surface of the liquid in the latter a foot or so, is retained there until digested, and is then drawn off by a sludge pipe in the bottom.

With a few feet of fall to the sludge bed, there is seen to be no necessity for pumping the sludge, the movement of which is controlled by valves.

The tank is designed especially for fresh domestic sewage, such as is produced in small towns or cantonments, with an effluent, after a detention of from 30 to 50 min., still relatively fresh and containing dissolved oxygen. To obviate the difficult and objectionable removal and disposal of scum by hand, this is readily disposed of with the sludge. A further advantage lies in avoiding the excessively deep excavation usually necessary with the Imhoff tank.

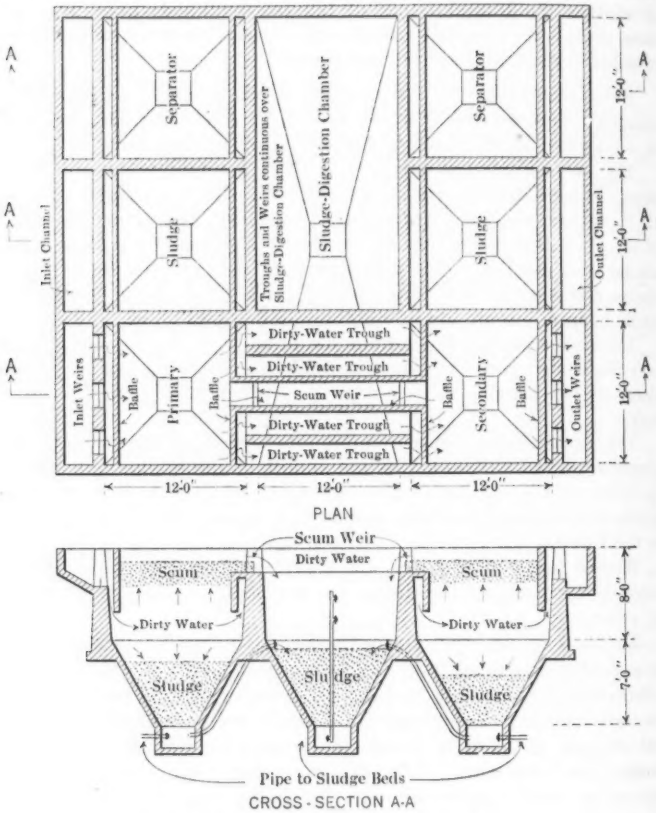
A tank of this description has been in continuous operation at the Great Lakes Naval Training Station since October, 1917. It consists of three units, each designed to handle 1 000 000 gal. per day, with a detention period of 45 min. in each tank. It is understood that there has been no appreciable accumulation of sludge at this plant, and that it has been very successful in operation. The small quantity of sludge has been attributed to an increased fermentation due to

* New York City.

Mr. Allen.

an occasional seeding with a wisp of hay, but this is not believed to be proved as yet.

The speaker does not know what difference there is between the character of the sewage at these works and that at the cantonments.



TYPICAL POSITIVE SEWAGE SEPARATOR AND DIGESTOR
FOR FRESH SEWAGE
1000-HOUSE DEVELOPMENT
FOLLOWING PRINCIPLES PROPOSED BY JOHN W. ALVORD - CONSULTING ENGINEER

FIG. 6.

The plants of the Housing Corporation have not been operating long enough to reach a determination, but that at the Great Lakes Station has been in use for more than a year, and, thus far, seems to have given good results.

Mr. Allen.

With reference to the Great Lakes plant, the following additional information has been received from L. R. Howson, Assoc. M. Am. Soc. C. E., who has been intimately connected with its design and operation:

"The writer visited the Great Lakes Station on Thursday of this week—the day before your letter was received.

"The tanks have been practically free from odor, even in the immediate vicinity of the plant, and entirely free from odor at a distance as great as 50 or 100 ft.

"The sewage is very fresh, the age of the sewage when it reaches the plant being from 5 min. to a little over an hour from point of origin to the time it reaches the plant. The average age is less than 45 min. This and its purely domestic character account for the formation of great quantities of scum and very little sludge. The scum forms to a depth of from 2 to 3 ft. per week over the primary tanks.

"The tanks have operated very successfully, and an average of approximately 80% of the suspended matter has been removed by these tanks alone.

"When the tanks were first placed in operation a strong hydrogen sulphide odor was observed. The chemist at the Naval Training Station did considerable experimental work to overcome this odor, and worked out some interesting data with regard to liquefying this sludge and scum.

"The sludge digestion chamber was also seeded with liquefying bacteria, with the result that the plant has now been in operation for a year and a half, operating the greater part of the time at approximately 50% greater rate than that for which it was designed, and, although the sludge has been discharged into the central digestion chamber at weekly intervals, it has not been necessary to draw off any sludge to the sludge beds to date, although the comparatively clear liquid resulting from the liquefying of the sludge has necessarily been disposed of.

"There have been some difficulties observed in the operation of the plant as a whole, which are not, however, attributable to the tanks. We had some 40 ft. of head to spare between the tanks, which are on the bluff, and the filtration plant at the foot of the bluff. This was utilized by aerating steps, which we considered and showed on our plans as being desirable for use at certain seasons of the year and when the wind was off-shore. The base hospital with its additions are within 300 ft. of the sewage disposal plant, and it must therefore operate entirely free from odor at such time as the wind is blowing on shore and from the plant toward the hospital buildings. The only complaints from odors which we have observed have been due to the use of the aerating steps, and these have been very slight. The use of the steps is now discontinued, and they will not be used except during favorable wind conditions."

Plants of this type have been built at Madison, Wis., Aberdeen, Md., Bethlehem, Pa. and Swedeland, Pa.

Mr. Kershaw.

G. Bertram Kershaw,* M. Am. Soc. C. E. (by letter).—This paper brings out the marked difference between municipal and camp sewages,

* London, England.

Mr. Kershaw.

the latter not only being considerably stronger, but, in addition, containing considerable grease.

It may be of interest, for purposes of comparison, to give some figures of analysis for an ordinary domestic sewage and for a barracks sewage, the latter in Great Britain differing but litttle from camp sewage. The following figures relate to the average of three sets of hourly samples, taken at the Aldershot Camp Sewage Farm:

	Parts per 100 000.	Parts per 1 000 000.
Ammoniacal nitrogen	7.87	78.7
Total organic nitrogen	5.06	50.6
Albumenoid nitrogen	1.62	16.2
Total nitrogen	13.3	133.
Oxygen absorbed in 4 hours	20.79	207.9
Chlorine	14.98	149.8
Suspended solids	36.6	366.

The Caterham Barracks figures were obtained from the average of four sets of hourly samples, and are even stronger:

	Parts per 100 000.	Parts per 1 000 000.
Ammoniacal nitrogen	31.41	314.1
Albumenoid nitrogen	1.75	17.5
Total organic nitrogen	3.87	38.7
Total nitrogen	17.53	175.3
Oxygen absorbed in 4 hours	17.99	179.9
Chlorine	13.57	135.7
Suspended solids	42.10	421.

The sewage of Kingston-on-Thames may be regarded as an average domestic sewage, and the figures are also obtained from sets of hourly samples, drawn according to rate of flow.

	Parts per 100 000.	Parts per 1 000 000.
Ammoniacal nitrogen	3.85	38.5
Albumenoid nitrogen	0.86	8.6
Total organic nitrogen	1.63	16.3
Total nitrogen	5.49	54.9
Oxygen absorbed in 4 hours	10.66	106.6
Chlorine	9.43	94.3
Suspended solids	31.	310.

The foregoing figures demonstrate the strength in nitrogenous matter of camp sewages as compared with domestic sewages, and this is due no doubt to the fact that, as the author points out, the population is adult, and, further, the quantity of nitrogenous food consumed is large. The same thing has been observed in Great Britain, in the case of colliery towns and villages; in these cases, however, the water supply is often low.

Mr. Kershaw.

During the first stage of the war, considerable difficulty was experienced here with grease, and specially large grease traps were put into use for intercepting it. Disinfectants, too, were often used in sufficient quantity to interfere materially with biological purification. Grease, however, was the chief difficulty, and, as might have been anticipated, it caused trouble at all stages of treatment, while it was some little time before steps were taken to utilize the grease recovered.

In the early stages of the war, many of the camp sewage treatment works left a great deal to be desired, both as regards design, and ability to cope with the very concentrated sewages. Moreover, in some instances, several small treatment works were constructed, where, with a little ordinary engineering skill, one plant would have sufficed.

In the camps in Great Britain, it was found that the sewage flow was almost invariably divided into distinct flushes, the flow being practically confined to about from 10 to 12 hours out of the 24. Consequently, when the filter capacity was calculated on the basis of the sewage flow of an ordinary town, at a rate of, say, 75 gal. per cu. yd. per 24 hours, it was about 50% too small. This fact was often lost sight of at first.

With respect to water supply per capita, the figures given by the military authorities were usually found to be much too low, and 30 gal. per head was determined as being about right, in fact, it was the usual figure taken for a town water supply.

With regard to manholes, it is the customary rule in England, that the distance apart shall not be in excess of about 300 ft. Some years ago, lampholes were permitted between the manholes, but, lately, they have been discouraged by the Local Government Board. In the case of the majority of the camps, full treatment by tanks and filters has been carried out, as conditions were seldom such as to warrant the discharge of tank liquors without further treatment.

The following details of a plant designed to deal with a total sewage flow of about 20 000 gal. per day, may be instructive, as showing that the treatment of a strong camp sewage is by no means a simple matter:

1. Grease trap.
2. Covered septic tank, capacity about 15 000 gal., with inverted pyramid bottom for removal of sludge.
3. Small mixing tank for chemicals.
4. Four fill and draw settling tanks, capacity of each about 5 000 gal., with floating arms and sludge valves.
5. Two dosing tanks, capacity of each about 200 gal.
6. Two deep percolating filters of coarse coke or clinker, capacity of each about 250 cu. yd., with automatic distributors.
7. Effluent settling tank, capacity about 2 000 gal., with inverted pyramid bottom for removal of humus.

Mr. Kershaw.

8. General sludge sump, provided with chain-pump, and communicating with septic tank, settling tanks, and effluent settling tank.
9. Two shallow effluent straining filters of fine coke or clinker, each about 20 sq. yd. in area and 9 in. deep.
10. An area of land set aside for trenching the sludge, which would be considerable in volume.

This is a specification written by Maj. C. C. Frye, one of the chemists to the recent Royal Commission on Sewage Disposal.

The writer is unable to follow the author's statement that, "the capacity of a trickling filter does not vary directly with the volume of filtering material, a 5-ft. filter giving as good results as a deeper one." Surely this depends very largely on the size and character of the filtering material used; in other words, on the duration of contact of the liquor with the filtering material.

Comparison of the work done even by similar filters, with similar distribution, is beset with pitfalls. For example, a 5-ft. filter (*A*), may be working below its full power and producing a good effluent at a certain given rate of filtration per cubic yard; it would be erroneous to dose a 10-ft. filter (*B*), at a rate three times that of Filter *A*, and, because it produces an effluent similar to that of Filter *A*, to assume that Filter *B* can treat three times as much as Filter *A*, as Filter *A* is not working up to its full capacity; this destroys any comparison.

Concerning continuous and intermittent distribution on filters, it is to be observed that if the tank liquor is applied to filters not continuously, but in flushes, this must result—other things being equal—in increasing the volume treated per cubic yard in a given time. It would seem to be most desirable, in comparisons of treatment plants, to give the numerical figure of strength of sewage dealt with in each case.

Mr. Besselievre.

EDMUND B. BESSELIEVRE,* ASSOC. M. AM. SOC. C. E. (by letter).—The subject-matter of this paper is of great interest to the writer as he has specialized in sewage treatment, and, therefore, it possesses a peculiar claim on his attention. He also had the opportunity of being associated with the author, during the last year of the war, in the solution of sanitary problems at the various camps and cantonments of the United States Army.

The salient points of the paper which appeal to the writer, and which it is his intention to discuss, are the striking variations in composition between ordinary municipal sewages and those of the camps; the conditions entering into the selection and development of a proper type of tank for treating this sewage; the need for careful design of

* Washington, D. C.

tanks and auxiliary units; and the necessity for careful operation of the tanks and co-operation between the designer and the operator. Mr. Besselievre.

The writer feels that the author has covered, clearly and satisfactorily, the question of reasons for adopting the single-story tank instead of the type which had been most commonly used by nearly all civilian engineers previous to the war. It is only fair to state here that previous to the writer's association with the Construction Division, he felt, as did the majority of sanitary experts, that the two-story, or Imhoff, tank was productive of the best results for all municipal sewage problems. However, a careful consideration of the subject and a thorough understanding, gained by personal investigation and observation at various camps and the study of reports of results, etc., has changed this opinion to a great extent.

The conditions peculiar to the production of camp sewage were so different from those of ordinary municipal work that, considering these conditions and the need for speedy construction and economy in cost, it was seen that a single-story tank with some modifications from the older types of the septic tank would be the most reasonable one to adopt.

The life and habits of the soldier are regulated by strict discipline, producing a great tendency toward unusual concentration, at certain short periods, of the usage of sanitary facilities. This established a peak load in the sewers higher in all cases than in those of any municipality of which the writer could find record; and, also, due to the controlled usage of water, produced a high concentration of the sewage itself. Owing to the congested housing conditions and comparatively short length of run to the point of tankage, the result was a fresh, practically uncomminuted sewage, with a high suspended organic solid content.

Naturally, in comparison with a sewage traveling a relatively long distance and one that is more dilute and, due to length of flow, highly comminuted and partly septic, the first mentioned, or camp, sewage would require, regardless of any consideration of the composition of the diluting water, a tankage of greater duration in order to allow of proper and sufficient deposition of suspended and settleable solids during the passage through, and greater provision for the retention and digestion of the resultant deposit. These were the basic principles of the tanks designed and built by the Construction Division, under the author's direction.

The writer was greatly astonished when, during a study of the constituents of municipal sewages and those of various camps, the tremendously high, suspended, organic solid content of the camp sewages was made apparent. The data on page 343, showing averages only, do not indicate the maximum; but with an average of 750 parts

Mr. Besselievre.

per million of suspended organic solids, it can be easily assumed that the maximum was considerably higher.

As this average is so much greater than that for any municipal sewage of which the writer has had reports, it does not require, in his opinion, any further arguments to show the necessity, to any sanitary engineer, for a tank different from the usual municipal type, disregarding for the moment the considerations of speed of construction, cost, and the temporary character of the camps.

In either camp or municipal practice mere excellence of design does not necessarily guarantee satisfactory results. To the writer fully 90% of the production of a satisfactory, unoffensive tank effluent depends on the intelligent operation of the unit, based on the recommendations of the designer and a thorough understanding of the principles involved in each particular design.

Unfortunately, in quite a few cases, the tanks built by the Construction Division, despite all precautions and recommendations, did not have the co-operation of operator and designer and, due to this, there were several instances where, in two places, similar tanks working with sewage of like character gave results nearly diametrically opposite.

During the past 13 years, the writer has visited professionally a majority of the sewage treatment plants in the United States, and observations at these places have strongly embedded the conviction that the principal cause of failure in the production of satisfactory results is due to faulty operation.

Excellent design, embodying careful consideration of all conditions, has been negatived in several cases by the lack of intelligent operation or intentional neglect, due either to want of interest or knowledge on the part of the municipal authorities, or to the natural stupidity or laziness of the operator who has been selected in all probability for political reasons rather than for his ability to operate the plant as intended. On the other hand, plants improperly designed were, nevertheless, due to careful and intelligent operation, capable of producing the results intended at the time of design.

Despite the military discipline at the army camps, it was not possible, in all cases, to obtain the degree of control desired by the engineers of the Construction Division. Lack of knowledge of the principles involved in the design or proper operation, coupled with the sad fact that the average layman considers, usually erroneously, that a sewage disposal plant is a disagreeable place in which to work, and the supposition that intentionally faulty operation would secure release from such a detail, may have been the causes contributing to the trouble in the few cases in which it arose.

The writer is a strong advocate, in all cases where sewage treatment plants are built, of having it distinctly a part of the engineer's contract that not only is he to design and supervise the construction of the

plant, but he is to have the selection of the attendant and be responsible for his proper instruction. He should make periodical inspection trips to the plant for a certain specified time in order to ascertain whether all instructions are being carried out and the desired results obtained. Mr. Besselievre.

In the field of plant operation and control, the State of New Jersey has undoubtedly taken a long step forward by the passage of a license law for operators of sewage disposal plants. This law provides for intelligent operation, and the unique Sewage Works Association of New Jersey has been one of strongest advocates of such legislation and has done more than any other organization to bring it about and thereby place New Jersey as a pioneer in this phase of engineering, the intelligent operation of public utilities. It would be well if other States followed her example in this regard.

In the determination of the retardent action of grease on proper septic tank action and sludge digestion and the formation of non-soluble scums, a long step forward was taken by the adoption of proper grease-retaining traps, either at some point near the septic tank or, as in the later work, by separate traps at each kitchen or group of kitchens. The results obtained in the operation of tanks and filters after the removal of the grease content, have more than justified the opinion of the detrimental action of grease, and their cost has been a minor item compared with the beneficial results and the reclamation value of the grease obtained from these traps before its pollution by sewage.

Instances have been known where a tank which had been operating indifferently before the removal of the grease, would show entirely different and eminently more satisfactory results, after it had been thoroughly cleaned and the grease traps introduced. In view of the results obtained, the writer feels that, for the sake of obtaining better and more rapid sludge digestion, freedom from scum, and the protection of sprinkling filters, some form of grease-retaining device should be introduced, regardless of the reclamation value of the grease obtained.

It is, of course, manifestly impracticable in municipal work to introduce a grease trap in each house, as this would make necessary the construction of some central grease-retention device. This would eliminate any reclamation value of the grease, as it would be polluted by sewage and, therefore, worthless, but the increase in efficiency of the tank would more than offset the slight additional expense of the trap.

In one case with which the writer is familiar, namely, a camp in the District of Columbia, the average weekly total accumulation of grease removed from the traps in the camp, which was a small one, was 2 000 lb.; and after a small soap-making plant had been set up, the authorities were able to make sufficient soap from this grease to supply all the kitchens and laundries in the camp.

Mr. Besselievre.

In line with the author's call for further research and development work with a view to the procurement of more satisfactory plants, the writer desires to elaborate on several features of design, which, not having been given the necessary study, have caused trouble in a number of municipal plants inspected by him.

In referring to the design of units of a sewage treatment plant, the writer wishes to call attention to a particular feature in connection with the design of dosing tanks for sprinkling filters, which has been brought strongly to his attention by visits to more than 150 municipal plants in the United States and the observation of their failure to function properly due to lack of proper attention to this detail.

Although the dosing tank is a small unit of a sewage treatment plant, and is, the writer fears, one that is usually passed over hurriedly in design, it is, nevertheless, one of the most important units, and unless proper and intelligent design is made, an otherwise well designed plant can be made very inefficient.

If the dosing tank is not properly proportioned to the volume of flow to be handled, the filter may be improperly dosed and a negative result secured in the filter effluent.

Regardless of the length of the dosing period, the capacity of the tank, its shape, and general features of construction, the method of connection to the filter distribution piping should be given careful attention and study.

The size of the tank should be proportioned to the dosing period and the inflow, so that the volume discharged during the total discharge period will not be excessive during abnormal flows. Therefore, a careful selection of the dosing apparatus should be made so as to provide for the drawing down and "breaking" of the siphon action at the predetermined low-water line, regardless of the rate of inflow.

The writer has seen numerous municipal plants wherein this point has not been carefully considered and, due to insufficient siphon size or nozzle capacity, the siphon at times of maximum flow would go into continuous operation, with the consequent flooding of the filter for periods of hours. This results in canalization of the effluent through the filter material and the production of negative results as to purification of the effluent. A careful study of this point, with a proper use of the data provided by the manufacturers of siphons and nozzles, will tend to eliminate the trouble which may be caused very easily by neglect of this particular feature.

Another important feature in the design of a sewage treatment plant, and one which although not exactly in the dosing tank, nevertheless applies to it, is the consideration of the means of connection between the siphon mouth and the distribution system of the filter. Neglect of the importance of this point and improper design has caused, to the writer's knowledge, the failure of several municipal plants.

Mr. Besselievre.

Failure to design this connecting link properly has resulted usually in the loss of the most valuable head in the dosing tank, namely, the first few inches or first foot. Such loss is due to laying the pipe connecting the siphon mouth with the distribution system above the level of the nozzle orifices so that after each discharge of the siphon this piping was drained and at the next discharge, sufficient liquid was required to fill this empty piping before the water would appear at the nozzles. This was sufficient to reduce the head in the dosing tank to such an extent that the radius of nozzle spray, in turn, was reduced to a few feet from the nozzle, leaving the filter with a very large percentage of unwetted area.

The effect of such a small radius spray is an overdosing of the portion of the filter immediately adjacent to each nozzle and tendency to canalization of the liquid through the filter without proper bacterial action.

In one particular municipal plant, with which the writer is familiar, the loss occasioned by this feature was such that with a dosing tank having a draft of 24 in., the loss of head, due to improper layout of piping, was 10 in., and the resultant radius of spray was about 4 to 5 ft., whereas the design of the plant was based on a radius of 11 to 12 ft.

In all cases, the discharge piping after leaving the siphon mouth should be dropped at once to such a level that the top of the pipe will be below the elevation of the lowest nozzle on the filter bed. It is impossible, of course, to get all the piping below the nozzle orifice, but with the drop beginning immediately after the vent connection at the siphon mouth, the minimum amount of piping will be emptied; the volume of this piping may then be ascertained and allowance made in the design of the tank so that the first inch or two from the top will contain sufficient liquid to fill this empty piping without the loss of the most valuable head of all, the initial head.

This consideration of the layout of the piping between the siphon and the filter is all the more important when a long period of dosing is used, with a corresponding long period of filling, during which period the piping is draining. With a short dosing period and a short filling period, the draining period is of necessity also shortened, and the emptying of the pipe lessened, so that the harm in this case is reduced; but, nevertheless, regardless of the length of the dosing period, this point should be carefully considered.

In closing, the writer desires to state that he believes that the type of tank and plants described by the author, for conditions similar to those found in army camps, when properly operated in accordance with the ideas and opinions of the designer, have given eminently satisfactory results.

Mr. Hammond.

GEORGE T. HAMMOND,* M. AM. SOC. C. E. (by letter).—This paper should prove of much interest to the Engineering Profession. It sug-

* Brooklyn, N. Y.

Mr. Hammond.

gests the way to simpler methods of sewage and wastes disposal, and to further research work along certain practical lines. It also gives an interesting insight into some of the sanitary problems which had to be solved, under much stress and haste, by the engineers of the United States Army.

During 1918, and the first part of 1919, the writer was afforded an excellent opportunity to study, at first hand, some of the structures and methods which are described in this paper. He was not only able to make numerous visits to many of the cantonments and camps, but, in the course of his duties as an engineer, he was called on to design and erect several similar structures and to observe their operation.

During the period previously mentioned, the writer was in the service of the United States Government, at first as Sewage Disposal Expert and Sanitary Engineer to the United States Shipping Board, Emergency Fleet Corporation, on the staff of Morris Knowles, M. Am. Soc. C. E., Chief Engineer, Passenger Transportation and Housing Department, and had charge of the preparation of standard specifications for, and reports on, the sewage disposal of the industrial housing projects, as well as the review of plans for such structures. In many instances, these projects were large towns, some of which contained more than 2 000 houses. Like the cantonments, they had to be built in the utmost haste, and some of the problems met were quite similar, though on a smaller scale. Similar questions in sewage disposal arose, and, in several instances, the Doten plans for disposal plants and for grease traps were adopted. As Consulting Engineer, the writer has recently been in touch with these plants and is able to state that they are giving satisfactory service.

Following his service with the Housing Department, the writer was assigned to the staff of Lt.-Col. P. S. Doane, U. S. A., Director of Health and Sanitation of the U. S. Shipping Board, and was placed in charge, as Sanitary Engineer and Health Officer, of District No. 2, extending from Providence, R. I., to Camden, N. J., and containing thirty-five shipyards. Later, this department was by order of President Wilson, transferred to the U. S. Public Health Service, Assistant Surgeon-Gen. L. L. Lumsden succeeding Lt.-Col. Doane, as Director, under whom the writer continued to serve. While thus engaged, he had to provide a number of structures very similar to those described in this paper.

The writer came to regard the sanitary problems involved from much the same standpoint as the author, and to follow about the same methods in their solution, especially as certain designs and structures adopted under emergency conditions had proved, with properly regulated service, to be more successful than was expected and could be constructed quickly and cheaply.

Mr. Hammond.

The sanitary requirements met in the shipyards, and in the housing projects connected with them, arose mainly from the great number of men suddenly brought together in places where all utilities were absent, until provided, for housing or feeding them, or otherwise caring for them. The shipyards sprang up like mushrooms wherever a ship could be built and launched, often at places quite distant from cities; and the progress of these yards was quite wonderful. Where a few hundred men were at work one day, thousands might be working within a week; probably more than 500 000 men were engaged at one time in shipbuilding.

In the shipyards of District No. 2, there was at one time an aggregate of more than 100 000 men. In several yards, there were more than 10 000 men each, and in one more than 15 000. Dormitories, mess halls, restaurants, and other houses had to be erected, with the attendant sanitary arrangements, and water supply, sewers, and sewage disposal facilities had to be provided in haste.

The paper discloses only a meager outline of the difficulties overcome by the War Department, in that hurried rush to put our military house in order. Much might be said about it. Those who saw this effort under way will never forget what a tremendous achievement it was, or how well the organization created for this great service succeeded in its work. Yet, it is also true that the undertaking was even more vast than was realized by those engaged in it. We should never again permit our country to be caught in such an unprepared condition. The results achieved in getting ready our army, our ordnance, and our ships, seem scarcely less than marvelous. The credit for this result, so important to our country and to civilization, belongs, in a large measure, to American civil engineers who went at once to the assistance of the Government.

It was the writer's privilege to visit the sanitary utilities at many of the cantonments, and he believes that, making due allowances for the uncertain factors which the problems presented to the engineers who designed them, they were remarkably successful. There was, however, at least one mischance to regret. Many of these structures were not large enough for the service which became necessary soon after they were installed. The rapidity and volume of mobilization in the camps was not fully anticipated, and the factors of safety in the capacity of the sanitary structures were small. Water supply, sewage disposal, and some of the other camp utilities, were not designed on a liberal scale, and it happened, sometimes, that where provision had been made to serve not more than 25 000 men, a service for 50 000 was necessary within a few weeks of the date of completion.

The writer in his various visits did not at any time see these utilities of too large a size, and, frequently, they were not large enough to meet the requirements. It was so easy to send men to a camp by the

Mr. Hammond.

trainload and make extra accommodations, if necessary, for them, and so difficult to extend the water supply and the sewage disposal plants, that it was not surprising to find the latter overloaded and put out of service by this unexpected burden. Under these conditions, the quantity of sewage probably did not increase as much as might have been expected, in proportion to the enlarged population, or as much as the quantity of suspensa which it carried, and especially the quantity of fats.

The sewage being treated by the disposal plants was the strongest the writer has ever seen, and it was very fresh, causing the tanks to clog rapidly with scum and fail to function as treatment units, unless the scum was removed frequently, such removal in some cases being required daily.

It was unfortunate, in view of this experience, that a larger provision was not made in the design of these utilities for increases in camp population beyond the first estimates. In all the sanitary structures, a liberal policy in expenditure would have been justified, as the health and comfort of the men in training was of the greatest moment, and the extra cost required to provide for contingencies would have been only a small proportion of the total cost of the camps.

In providing sewage disposal plants for the housing projects of the United States Shipping Board, Emergency Fleet Corporation, account was taken of the probability, or at least possibility, that the villages would be occupied long after the end of their emergency use; that they would afford permanent homes for families; and, in many cases, would be absorbed into neighboring cities and towns. The utilities, therefore, were put in with this in mind, but with all possible economy. Wherever the sewage could be led to existing plants, this was done. If conditions were proper, the disposal of sewage was by dilution; but there were several places where tank treatment was absolutely required, and the choice lay between septic tanks, Imhoff tanks, and Doten tanks. For these villages, the septic tank was considered improper, and, after much discussion, the Imhoff tank was rejected as not advisable. Granting their well-known excellent points, it was decided that Imhoff tanks should not be erected if the plant was to be within smelling distance of the dwellings, especially when treating such fresh sewage as would be the case at these villages.

Under the most favorable conditions, the Imhoff tank is the most costly of all types to build, as well as the most costly and difficult to operate successfully. It requires from six months to a year to ripen thoroughly and is never free from the danger of "frothing" and creating a nuisance. When these tanks give trouble, they are worse than useless, and that they frequently do give trouble, periodical literature abundantly shows. For very fresh sewage with much grease, the writer considers them inadvisable. Small installations are especially likely to give trouble. In all cases, the plants at these villages would have

Mr. Hammond.

to be near houses occupied for residence purposes. Nevertheless, in one instance, an Imhoff tank already built was used, and did not make its kind any more popular by its performance. In another instance, a city of considerable size joined with the industrial city in building a battery of Imhoff tanks, the writer, at the request of Admiral Bowles, acting for the Shipping Board, with the consulting engineer employed by the city and for the project, in selecting the design. This plant is not yet completed. It was located, however, so that complaints are not anticipated on account of odors; should odors arise—and the plant is large enough to expect that—they will be given proper care.

The "Doten" tank had been adopted for the military cantonments, and many such tanks were already in service. One was erected at Camp Meade, where it was operated under the Constructing Quartermaster, who, at the time, happened to be Maj. E. B. Whitman, M. Am. Soc. C. E., a former associate of the writer on the Baltimore Sewage Commission. The writer visited Maj. Whitman and was able to make a study of the tanks, which, designed for about 25 000 men, had clogged and failed to function under the load of about 50 000. One learns most about a tank by seeing it act badly; we all learn by such failures. What the writer learned by observing the Camp Meade tanks in distress, convinced him that the type had some good points; at least, it would not froth and boil over like the Imhoff tank under similar conditions, and it did not smell unless disturbed.

It was after several visits to Camp Meade that the writer became acquainted with the author, who kindly gave the officials of the Shipping Board many data concerning the design and characteristics of the Doten tank.

The first impression of this tank was certainly discouraging; but a long experience in sewage experimentation suggested the idea that it was doing better than should be expected under the conditions as seen. Arrangements were effected whereby the writer was enabled to visit and study a number of these tanks in service at the various cantonment camps, among which were the following: Fort Myer, Camp Meade, Camp Holabird, Camp Dix, Camp Mills, Camp Merritt, Camp Upton, and several others.

The first visits made to these camps were in June and July, 1918, at a time when, in every instance, from two to three times the load designed for was being carried by the tanks, which were generally being blamed for failure to function by those who did not stop to reflect that any tank has a limit of capacity, beyond which it will fail. The writer felt convinced that, if treated fairly, they would not be failures. Indeed, he was much surprised with the manner in which these tanks carried the observed overload. The sewage was of extraordinary strength, coming from men only, highly fed, with a large proportion of meats. The sewage was not only very strong, but it carried a heavy

Mr. Hammond.

grease content and a vast quantity of fresh scum-forming materials. Under the conditions observed, these tanks filled with scum, cemented together with grease, which could only be got rid of by removal from the top. The sludge was removed without trouble from the hopper bottoms by the sludge pipes, and was dried with only slight, if any, odors on the drying beds. The heavy scum, however, which would not sink, of course, did not get down deep enough to reach the sludge pipes.

The scum trouble was caused mainly by the grease; when this formed about the floating solids, they rose to the top. The mass of scum became a solid cake, which, on being removed, required burial in trenches in order to prevent a nuisance. To meet this difficulty, Maj. Doten introduced the grease trap described in his paper.

After observing the cantonment camp sewage and other conditions, the writer came to the conclusion that an Imhoff tank would have clogged and failed sooner under this excessive and abnormal service, and that, of the two types, the Imhoff tank probably would have caused a greater nuisance and would have been the more difficult to clean, as it would have become filled with fresh settled matter, below and above, and covered with fats long before digestion could have been established. It would never have had a fair chance to function properly. Indeed, in most cases, before a two-story tank could have been built and given time to ripen, so as to work normally, it would have been useless, as the war would have been over.

In the housing projects of the Shipping Board much fresh sewage, not unlike the cantonment sewage, was to be expected from restaurants, etc.; and it was believed that the Doten tank would give as good, if not better, service than the Imhoff tank.

It is probable that a self-cleansing fine screen, placed ahead of either of these tanks, would have made a great difference. With such a help, perhaps an Imhoff tank would have worked successfully, and the capacity of either tank might have been more than doubled. In some places, if not in most, a fine screen would have afforded sufficient treatment without the aid of tanks; but the grease problem would have given the apparatus much difficulty until it was overcome.

One of the most interesting items included in the paper is the tank or trap used by the author to overcome the grease difficulty. The grease carried by the sewage, as already stated, was remarkably great in volume. Numerous determinations of this include an average of 150 parts per million for all the plants.

The writer was informed of instances at various cantonments in which more than double this quantity had been noted. This is about ten times the usual quantity found in ordinary domestic sewage, and its effect was to fill up the disposal tanks with floating solids embedded in a grease cake. With this condition, no tank could function properly.

Mr. Hammond.

Unlike ordinary floating solids, the grease was carried past the baffles and over weirs, so that it spread from the inlet to the outlet compartments of such plants as that at Camp Meade. Moreover, it passed through a cycle of changes which caused an acid condition in the tank, and bad odors when it was cleaned. Grease trouble was encountered at all the plants visited by the writer late in June and early in July, 1918, and he was enabled to see some of these plants in the process of being cleaned.

The grease traps adopted at first were formed of a chamber about 18 in. in diameter and 30 in. deep. As about four cans of very hot dish-water had to be discharged from each kitchen, after each meal, each as large as the "trap" it had to pass through, such a trap was useless. To meet this difficulty, the grease catcher or trap described by the author, was designed and built with good effect. After its construction, the work of the disposal plants was quite another story. Even though the tanks were heavily overloaded, the grease trouble practically disappeared, and, with it, to a great extent, the excessive scum formation. Moreover, the recovered grease was fairly clean, and sold for a good price. Many of these grease catchers were used on the writer's recommendation by the U. S. Shipping Board, not only in the industrial villages, where cafeterias and eating houses were provided with them, but, also, in connection with the restaurants and eating places in the larger shipyards.

No form of sewage treatment tank known to the writer would have operated successfully with this grease coming into it, least of all an Imhoff tank which would have had its flowing chamber clogged very quickly, and would have been in an acid condition throughout. It probably would have frothed and boiled over continually, causing active nuisance from sickening smells. It never would have produced "ripe" sludge. For sewage of the peculiar character and strength produced at the cantonments, after careful study of these plants, and by comparing them and the results obtained with other designs, the writer is convinced that the type selected was fortunate for the purpose. He agrees with the author that it is probably a fact that multiple-compartment tanks are more capable than any other form for protecting trickling filters and sand beds from grease carried in the sewage; but he also thinks that no form of tank will accomplish this object with entire success, unless an efficient grease catcher, or trap, is used as near as possible to the camp, or retaurant, kitchens, so as to take out the grease at the head of the line. By this method, 95% of grease can be recovered on the average, and sold at a profit; and if this is done, other forms of tanks might have a fair chance of success.

When operating within their capacity, under proper control, the author has shown that the Doten tanks effected a high degree of sedimentation. Even when grossly overloaded with sewage of unusual

Mr. Hammond.

strength, the effluent was usually well clarified. The removal of more than 90% of settleable matter from a sewage carrying 464 parts per million of organic solids, is certainly an excellent result.

When these tanks were first designed, there were probably few data on which to determine their size, even for ordinary municipal sewage, and it is very improbable that any one could have foreseen the character of the sewage they would be required to treat. The writer does not know of any digestion tank that will treat successfully the character of scum formed in these tanks, if saturated throughout with heavy grease which preserves the organic contents to a remarkable degree from digestion agencies. Such scum was, in its keeping qualities, not unlike the "pemmican" used by travelers and Arctic explorers. Solids would not settle while associated with this grease, so there was small chance either of digestion or sedimentation; even silt adhered to this floating mass.

The question may well be asked, To what extent may tanks of this form be expected to digest sludge? This is not easy to answer. That digestion of sludge and solids takes place in them to a greater or less extent, and under very unfavorable conditions, was evident to the writer in his examination of them. Leonard Metcalf, M. Am. Soc. C. E., has been quoted in a recent publication as saying that of those engineers who passed on the design of these tanks originally, only Maj. Doten believed that they would act as digestion tanks. Mr. Metcalf attributes the difficulty in the functioning of these tanks "to the fact that they were operated as digestion tanks". He says that the other engineers felt that they should be regarded essentially as sedimentation tanks, and, if so operated, they would do the work of clarification, and that was all that was thought necessary in the majority of cases. As clarifiers of sewage, there is no doubt of their success. The writer, however, does not think that the failures to function, which he saw, were due to their operation as digestion tanks. He has formed the conclusion that the cause of the trouble was overloading as sedimentation tanks. Up to the time when trouble occurred, the tanks operated in their own way without intelligent care, neither as sedimentation nor as digestion tanks, without regard to their capacity for either purpose, and without the removal of the scum until they were clogged. With the great volume of sewage pouring into them, carrying from 150 to 200 parts per million of grease; with 464 parts per million of fresh, settleable, suspended, organic solids entering at a rate of double and even triple their designed capacity, they were only about able to act as grit and scum catchers. Under these circumstances, there was far more flotation of suspended solids than sedimentation. They simply filled with grease and scum from end to end, as at Camp Meade, having merely a "convoluted passage" through them when thus filled, through which the sewage passed at a high velocity to the outlet. The

Mr. Hammond.

fact is, a tank designed for 25 000 men will not serve 50 000 men with success, even as a settling tank. No digestion was to be expected from tanks operated in this manner, and yet some did occur. In the Fort Myer plant, when it was working within its capacity, the digestion seemed to be very good, and a fairly ripe sludge was produced, which dried quickly on a bed, without odors. Since the plants at the various camps have been relieved of their great overload, and have been operated within their capacity, the writer is informed that good digestive activity is being shown at many places, and ripe sludge comparable with the best Imhoff sludge is being produced. This is the best answer to the question as to digestion. It would be interesting to give this, as well as the other features presented by these tanks, a more thorough experimental study. They have turned out in service much better than the writer would have expected, and show some advantages over other forms of tanks which, at least, makes them very interesting.

The Housing Department of the U. S. Shipping Board adopted a design of plant using these tanks, in which multiple units of full size were placed parallel with each other, the purpose being to keep one unit at a time in service on the daily sewage flow, until it had collected enough sludge and scum to interfere with its function as a sedimentation tank. It was then to be put out of active service and given a rest period, long enough to obtain complete digestion of the contents, when it would be discharged, the ripe sludge being dried on beds. Meanwhile, another unit would be in active service. In one plant, four such units were provided in a battery, and placed under the cover of one building. As a rule, at least two units were provided. How successfully this plan may work out, cannot be foretold, as the service has not been long enough in either of the plants to prove anything. So far, they are working very well. The first one to be put into its rest and digestion period has only recently been taken out of active service.

It has seemed to the writer that these tanks, which were designed for sedimentation and clarification of sewage, were not so well fitted for the digestion of sludge, and could not be depended on for this purpose. His reason for this is perhaps rather theoretical and derived from studies, made at the Brooklyn Experiment Station, on Imhoff tanks and separate digestion tanks, in which the results seemed to indicate that a complete separation of the sludge under digestion, from the flowing sewage, was desirable; and a minimum capacity, of 2 cu. ft. per capita below the slot lines, was necessary in the digestion chamber. This applies to Imhoff tanks treating domestic sewage, such tanks being not less than 24 ft. deep from the water line to the sludge outlet.

In the other tanks, however, conditions differ from the Imhoff tank. The series of compartments, baffles, weirs, etc., have a selective action

Mr. Hammond.

on the settleable solids, and the finer the organic particles, the quicker may digestion be accomplished. There is no such assortment of sizes in the Imhoff tank, in which the sludge is not ripe until the most resistant of the larger solids in it ripen. It may be true, therefore, that Imhoff tank digestion requires more time and more space than would be the case in the middle and outlet compartments of the Doten tank.

On the other hand, it seems doubtful whether the scum and settled matters in the first compartment of the Doten tank will digest in any reasonable time, because of their size and resistance to bacterial action, even when the tank is out of service and at rest. No digestive action is to be expected in this compartment while it is in active service; but if the grease in the scum does not prevent such action, hydrolysis and solution take place, and the dissolved materials are carried over with the flow of sewage to the next compartment, where it appears that digestion occurs rapidly.

Thus, it seems possible that if a tank of this type can be designed so that the first compartment is made of just the proper size for the flotation and hydrolysis of scum, which will not accumulate more rapidly than it can be dissolved and hydrolized, with the second and third compartments designed so as to afford a proper capacity for digestion, it might prove a very important acquisition to the sanitary engineer. The outlet compartment appears to have a marked effect in reducing the finely divided and dispersed organic colloids, giving a high degree of clarification. This is especially marked where there are more than three compartments in the unit.

Among the Doten tanks in operation examined by the writer, possibly the most successful was that at Fort Myer, near Washington, D. C. This tank was working at about its designed capacity and was producing a good and well-clarified effluent and an excellent quality of sludge, which was odorless and dried readily on a sludge bed. The effluent was discharged through a dosing chamber on a trickling filter bed of the character and design referred to by the author, as follows:

"The filter has an undulating floor, the distributor pipes being placed on the summits and pipe-covered gutters in the depressions. Thus, the expensive system of under-drains, which is usually an important feature in plants for municipalities, was eliminated."

The medium depth averaged 5 ft., and the size of stone from ¾ in. to 2½ in. The effluent was stable after 20 days, which is certainly a good result. Although the result of this design was good, and the cost low, the writer's experience and observation rather lead him to favor the standard design of placing the under-drains for all but very small plants like this one, at a minimum depth of 6 ft. for the medium. The absence of sufficient under-drains might cause clogging of the bed with humus during an "unloading period" of the filter bed. The design

Mr. Hammond.

adopted by Maj. Doten, however, has certainly given some good results, and is worthy of further study. If the cost of filter beds can be kept down by this method of under-draining, more filters will be constructed.

The time occupied in the closing cycle, in applying sewage to trickling filters, has been given much study by engineers. Continuous discharge on beds through fixed nozzles has not led to the best results. Plants using this method have never equalled the capacity per acre which has been secured by those designed for interrupted dosing, as obtained by intermittent applications, with dosing tank and siphon discharge, through sprinklers.

Experiments at Brooklyn gave the best results when the interval between doses was very short, but actual, and the dosing period was also short. A small siphon chamber proved to be the best. For this reason, the Brooklyn dosing chambers were reduced about 25% from the size first provided, thus increasing materially the permissible rate of sewage application per acre.

The limit of 2 000 000 gal. per acre, which the author thinks should not be exceeded, the writer believes to be low, and he would permit from 2 500 000 to 3 000 000 gal., with effective dosings of domestic sewage, on a bed 6 ft. deep. This figure depends greatly on the character of the sewage. He does not quite agree with the statement, as of general application to all conditions, that:

"The humus discharged from properly functioning trickling filters should not create an objectionable condition due to putrefaction. The putrescible character of the effluents from some deep trickling filters, and also the humus held in suspension, is due either to an inferior quality of tank effluent or to improper dosing."

The writer believes that the humus from all trickling filters is at times more or less putrescible. He has never seen an exception to this rule, and the reason for it, he thinks, has little to do with the tank or the dosing, unless this is very uneven or grossly improper. The main cause of it is the lower forms of life in the filter bed, such as worms, etc., which are frequently being discharged with the effluent and make up much of the so-called "humus"; the gelatinous casts that come away from the filter, which are often loosened by worms, are also putrescible, and when "unloading" takes place, as it usually does in the spring and summer, putrescibility of the suspensa in the effluent is one of its prominent features. Of course, it is admitted that improper dosing may possibly carry a stream of untreated sewage through the bed, or may cause unloading; also that highly septic sewage may affect the aerobic bacteria so as to start an unload; but, although these things are possible, they are infrequent. There is no doubt, however, that some of the best trickling filters in the world discharge a putrescible humus with their effluent. For this reason, secondary set-

Mr. Hammond.

tling tanks are necessary, except in small plants, or where the discharge goes into a large body of water.

The writer thinks that the plan of Messrs. Metcalf and Eddy, introduced at Fitchburg, Mass., of pumping filter humus back to the Imhoff tanks, is an excellent provision, as he knows of no way in which this humus sludge can be dried on a bed without causing bad odors.

Mr. Sherman.

A. L. SHERMAN,* ASSOC. M. AM. SOC. C. E. (by letter).—It has been the writer's privilege, during the past eighteen months, to be associated with the author in the design of the various structures connected with the sewage treatment plants at the different army camps and permanent posts throughout the United States, and the experience gained in overcoming the many difficulties encountered in this work has been very valuable. That the problem of successfully treating the concentrated, heavily grease-laden, army sewage has been practically solved is now generally admitted by those in touch with recent developments.

The early difficulties in the operation of the type of sewage tanks adopted for use in the army cantonments have been assumed by many to be functions of the tank itself, rather than an inherent part of the problem of treatment. The problem of treating a sewage containing 450 parts per million of suspended organic matter, including 150 parts per million of grease, besides an indeterminate quantity of garbage, was one which was new to sanitary engineers. The low unit capacity, 10 gal. per capita, used for the tanks first constructed, was selected with the realization that the great saving in first cost would be in part offset by increased cost of operation. It was also assumed that the maximum population, on which the 10-gal. unit capacity was based, would be reached only at intervals, and that the average would be much below this maximum. Lack of shipping and subsequent increases in the army programme resulted in the camps remaining at full strength during the entire winter and spring of 1917-18.

The removal of 70% of the suspended organic matter by sedimentation would result in the deposition in the tanks of 4.1 cu. ft., or 33 gal. per annum, of sludge containing 85% of moisture. This volume would be reduced perhaps 30% by digestion, or to 23 gal. per capita per annum. The grease alone, if entirely retained in the tanks, would amount to 19 lb. per capita per annum, or, on a 50% moisture basis, 38 lb., or 4.5 gal. of sludge due to grease. It should also be noted that the tanks were placed in use just prior to the winter season of 1917-18; they were immediately loaded above even their rated capacity, without any opportunity for a gradual "ripening", and were practically without attention for the ensuing six months. To the writer, the remarkable feature of the performance of these tanks is that they functioned at all.

* Mansfield, Mass.

Mr. Sherman.

As a contrast to the above, the results obtained during 1919, with competent operation, grease traps of the type described by the author installed throughout the camps, some minor changes in the design of the sewage tanks, and, in some cases, increases in the capacity per capita, furnish a more reliable index of the true value of this type of plant for sewage treatment.

The plant at Camp Merritt, N. J., which was used during 1919 as a debarkation camp for a large percentage of the troops arriving at New York City, is the most available one for inspection by members of the Society in and near New York City, and is a fair example of this type. The operation of the water supply and sewerage systems at Camp Merritt have been under the charge of Capt. Paul Molitor, formerly in charge of the operation of the sewage treatment plant at Chatham, N. J. Capt. Molitor has had in direct charge of the sewage treatment works, Mr. W. R. Teats, formerly of the Engineering Staff of the Pennsylvania State Board of Health, and they have taken great pride in the sewage treatment plant, which, contrary to the custom at many municipal plants, has been made attractive to the eye by grading, grassing, and the construction of gravel walks.

Capt. Molitor and Mr. Teats state that camp sewage is much more difficult to treat than municipal sewage, and that, on account of the large quantity of scum-forming material present, it would be practically impossible to handle the sewage in a two-story tank. This plant, during the spring of 1919, cared for the sewage of an average population of 26 000, with a gross per capita capacity of 28 gal., and a 95% removal of settleable solids.

The following extract from a recent report by Capt. Molitor is interesting, in view of various opinions expressed as to the ability of this type of plant to produce satisfactory digestion of sludge:

"During the month, 405 cu. yd. of liquid sludge was drawn from tanks to sludge drying beds. All of this sludge was of excellent quality, dark in color, practically odorless; in fact, no odors could be detected from it more than 50 ft. from the sludge drying beds. Weather conditions being favorable this sludge dried to forkable condition in from 5 to 7 days. The sedimentation tests show a high percentage of removal of suspended soils by the tanks, proving that if these tanks are operated with reasonable care and intelligence they will perform the work for which they are intended. No complaints have been received as to objectionable odors emanating from the plant. The plant continues to operate in a normal and satisfactory manner."

Mr. Brown.

J. F. Brown,* Assoc. M. Am. Soc. C. E. (by letter).—The type of sewage treatment plant adopted by the Construction Division of the Army for installation in the Army camps and industrial plants during the war, is so radically different from that ordinarily encountered in municipal practice that some discussion of the principles underlying its design and operation seems to be warranted.

* Kansas City, Mo.

Mr. Brown.

Maj. Doten has described in a general way the outstanding features of the standard sewage tank and the sections of the tank shown on Plate V give the details of the structure. It may be said that some of the details, particularly the rectangular sumps at the bottoms of the hoppers, are not typical of the standard design and are not found in any of the tanks serving the larger camps. The sloping baffle at the inlet end of the tank is another feature not typical of the earlier designs, having been adopted as a standard detail only after the recognition, on the part of the designing engineers of the Construction Division, of the presence of large quantities of grease in the sewage and the necessity of preventing the entrance of this material into the tanks. The original plans included vertical baffles at both the inlet and outlet ends, all compartments in any one tank were of equal dimensions, the slope of the floors of the hoppers was much flatter than that shown in Plate V, and there were no sumps under the lower ends of the sludge eduction columns.

In operation, sewage enters the tank at the water level and is immediately deflected downward by the inclined baffle. Particles of grease, and débris, such as match sticks, fruit skins, etc., which float on the incoming stream of sewage, are caught in front of the sloping baffle and may be skimmed off at frequent intervals, thus preventing the entrance of such materials into the tanks. The downward flowing sewage passes under the baffle and into the first compartment where, owing to the increase in area of the flow section and consequent decrease in the velocity of flow, the heavier particles of solid material are deposited. The lighter particles are carried on in the current under the vertical baffle at the outlet end of the first compartment, over the partition or weir wall and into the second compartment, where further sedimentation obtains. The same process is repeated in the third and fourth compartments, the effluent collected over the outlet weir into the effluent trough being practically free from suspended or settleable solids. It is the repetition of the sedimentation process, carried out in four separate stages, which accomplishes such a remarkable clarification of the sewage.

Many data are now available showing the results of extended tests of tanks in several of the larger camps, indicating the high efficiency of this type as a sedimentation tank, and it is hoped that Maj. Doten will publish them before his work in the Construction Division is concluded.

Coincident with the multi-stage sedimentation process is the multi-stage sludge digestion process which, unless the liquor in the tank has been "soured" by the products of decomposition of grease, has proceeded to a remarkable extent in many of the Construction Division sewage tanks. With the decomposition of organic solids and the consequent

Mr. Brown.

evolution of gas, particles of organic material which have been deposited in the inlet compartment, are comminuted or split up by the pressure of the gas generated within them. The gas thus generated rises into the liquor above the sludge, carrying with it partly digested particles of sludge. The finer gas-borne particles rising into the liquor are caught in the current of sewage and carried forward, either to be redeposited at a point nearer the outlet end of the compartment than that from which they were lifted from the sludge, or carried over the partition wall into the second compartment. The larger gas-borne particles ascend into the liquor above the sludge and continue to rise until the attached charge of gas is liberated into the air, when they settle again to the sludge layer. This process of comminution and carrying forward of the partly digested solids continues until the larger solids have been broken up into particles sufficiently small to be carried by the current over the partition wall into the second compartment.

In the second and in each of the succeeding compartments the process of comminution, gas generation, and carrying forward of the more finely divided particles continues, the final effluent from the tank being practically free from settleable solids, and the sludge accumulating in the final compartment being well digested and easily dried on sludge filters.

The inclined baffle at the outlet end of the fourth compartment is designed to deflect backward toward the center of the compartment the gas-borne particles that rise from the sludge deposits near the end of the chamber, thus preventing their passing out with the effluent, even at times when the digestive action in this chamber is progressing vigorously.

The most striking points of difference between the municipal sedimentation or digestion tanks and the standard Construction Division tank include improved arrangements for sludge withdrawal, a separate sludge eduction pipe being provided in each of the compartments, so that sludge can be withdrawn from any compartment; by means of the sludge pipes the accumulation of sludge in any compartment can be transferred into any other compartment for further digestion; and by means of the water pipe connection into the sludge line, the sludge accumulation in any compartment can be thoroughly agitated. These features facilitate the operation of the tank, the most important feature from this standpoint being the arrangement of piping in such a way that sludge can be transferred from one chamber to another. Although the normal processes of comminution and carrying forward of sludge particles tend to effect a restoration of sludge-storing capacity in the inlet compartments of the tank, it sometimes happens that, in periods of excessive sewage flow, or at times when the digestive action in the inlet compartment is weak, the accumulation of sludge in this chamber

Mr. Brown.

becomes excessive, and it is necessary to relieve the condition by transferring the sludge to one or more of the other compartments.

Important differences exist between the secondary treatment units and the auxiliary structures of the Army sewage plants and those of a similar type found in municipal sewage plants. The dosing tanks for all plants constructed in 1918 were designed for a holding capacity equal to the discharging capacity of the filter nozzles for 1 min., thus providing a maximum length of dosing period not exceeding 1½ min., at maximum rate of sewage flow. Several of the dosing tanks constructed in 1917 were altered during 1918, their capacity being reduced to this basis, a remarkable improvement in the filter effluent following each such alteration. Sprinkling filters were designed during 1918 with an effective depth of 5 ft., and with the exception of a few small ones treating sewage from Army hospitals, no filters were constructed of a depth greater than 6 ft. The areas of the filters were designed on the basis of treating the sewage from 30 000 persons per acre of filter, which is approximately equivalent to a sewage flow per acre per day of 2 000 000 gal.

The sludge filters, or drying beds, were much shallower than most municipal structures of this type, the total average depth of the filtering material being 15 in., made up of 12 in. of crushed stone and 3 in. of sand. The filters for sludge drying were not provided with concrete floors, nor were the inner slopes of the embankments paved. The under-drains consisted of vitrified sewer pipe laid in the depressions of the subgrade, each under-drain serving an area approximately 10 ft. in width. In designing sludge filters, an area of ½ sq. ft. per capita of population served was allowed. This was found to be ample; in fact, in one case, the sludge from the sewage tanks was dried with no difficulty on a very much less area per capita than that stated.

Secondary settling tanks were provided in a very small number of plants. These were designed with a holding capacity of about ½ hour's flow of sewage. Where disinfection of sewage effluent by liquid chlorine was carried out, the secondary settling tank was provided with a gas-tight concrete slab cover, water-sealed traps on both inlet and effluent lines, and in this tank the chlorine was applied to the sewage.

From January 1st, 1918, until March, 1919, the writer visited in his official capacity nearly all the sewage treatment plants installed by the Construction Division, as well as many plants installed by other Government agencies, and several municipal plants. Gross as has been the neglect of municipal sewage treatment plants—and every sanitary engineer knows that the operation of most municipal plants has been characterized by wanton neglect—the Army sewage plants fared even worse. During the latter part of 1917 and the early part of 1918, no definite military organization had yet been formed which would have charge of, and direct the operation of, the various camp utilities such

Mr. Brown.

as the water supply and distribution systems, the sewerage and sewage treatment plants, etc. Not only was there no skilled attention given to these plants, but even the most obvious needs were neglected. Sewer manholes were used as receptacles for cast-off clothing, kitchen garbage, and all sorts of débris; screen chambers, where these had been installed, were allowed to clog and fill to overflowing; sewage tanks were permitted to fill with accumulations of sludge and scum, and no attempt was made to keep the nozzles on the sprinkling filters clear. Even the most casual inspection would have shown the serious need of immediate attention. The one or two plants, notably the one at Camp Merritt, N. J., which were operated by attendants who possessed some experience in the working of sewage plants, were able to handle the suddenly varying and often excessive loads which came on them without any serious difficulty.

Early in the summer of 1918, with the organization of the Maintenance and Repair Branch of the Construction Division, many sanitary engineers were taken into this branch of the service, and placed in charge of the operation of the camp utilities. This arrangement brought about a marked improvement in the methods of operation of sewage plants, and in the months immediately following its adoption many of these plants were quickly brought into a satisfactory operating condition.

The writer has read with interest the discussions on Maj. Doten's paper. Some of the opinions stated therein are apparently based on observations made during the spring and early summer of 1918, when nearly all Army sewage plants were clogged and filled with grease, and in many cases all digestive action in the tanks had ceased, due to the acidifying of the liquid resulting from decomposition of grease. Up to this time, as previously mentioned, no effort had been made on the part of the local camp authorities to protect the tanks from the excessive quantity of grease discharged into the sewers from the camp kitchens, and the enormous quantities of débris and garbage which were wantonly deposited in the sewer lines. Under the better conditions resulting from the installation of efficient grease traps and coarse bar screens, and intelligent operation, the conditions have almost completely disappeared.

The writer questions the statement that efficient tank treatment may be accomplished by the so-called two-story tank, especially if such a tank were to be used for the treatment of fresh, concentrated, grease-laden camp sewage. Reports of the conditions of Imhoff tanks in several of the Army Aviation Fields covering the first half of 1918 do not indicate that any considerable success was attained in their operation. In fact, it was found that these tanks were absolutely inefficient both as sedimentation tanks and as digestion tanks.

Mr. Brown. While admitting that it is the consensus of opinion that the effluent from a septic tank cannot be treated by processes of bacterial oxidation —such as filtration through trickling filters—as advantageously as one which is not effected by the products of decomposition of sewage solids, the writer believes that the arguments advanced in support of this opinion are academic in their nature, and are not borne out by facts. He is of the opinion that the results of the series of chemical analyses made by the Bureau of Chemistry of the Department of Agriculture on both tank and filter effluents at the Fort Myer plant, which were quoted by Maj. Doten, indicate the fallacy of this opinion. It would appear, by logical deductions from the results of these tests, that the processes taking place in the Fort Myer tank rendered the effluent especially susceptible to treatment on a trickling filter. Maj. Doten has apparently reached a similar conclusion regarding the success attending the treatment of the effluent from a tank of the Construction Division type on a trickling filter. Additional evidence supporting this conclusion can undoubtedly be collected by a study of existing records of chemical analyses of such effluents, and it is hoped that Maj. Doten will present at least a summary of the data found in these records before the discussion of his paper is concluded.

Mr. Perry. LYNN E. PERRY,* ASSOC. M. AM. SOC. C. E. (by letter).—The first tank built by the Construction Division of the Quartermaster Corps which the writer had the good fortune to inspect was at Fort Myer, Va. This was in May and June, 1917. When his attention was first drawn to it, it was under construction, but was rapidly completed and placed in operation. The writer's opinion was that it would act as a clarification tank rather than as a sludge digestion tank. Its remarkable efficiency as a settling tank impressed him forcibly; especially as he remembers very distinctly, that the effluent was turned on the sprinkling filters when they were little more than one-third filled with stone. At that time, the effluent from the filters flowed through a very small ditch which showed no evidence of carrying an unstable flow during his stay at Fort Myer.

In discussing the design of this tank with H. C. McRae, Assoc. M. Am. Soc. C. E., at that time, the writer did not believe that the advantage of the pyramidal bottom was commensurate with its cost; it was not sufficiently steep to force the sludge down, although it was too steep for men to stand on while cleaning the tank.

After reading Maj. Doten's paper and learning that an attempt has been made to obtain efficient digestion in these tanks, the idea has occurred to the writer that probably better results might have been obtained if the tanks had been constructed so that the flow could be reversed, horizontally. This has been done in some recent designs of Imhoff tanks and although the writer has not observed any consider-

* Easton, Pa.

able improvement, a logical attempt, at least, has been made to help the operator over his difficulties. Mr. Perry.

The writer cannot refrain from expressing his commendation to Maj. Doten for not adopting some form of the Imhoff tank as a standard of the Construction Division. Due to certain propaganda, almost all the laity and a large percentage of engineers regard the Imhoff tank as a panacea for all sewage ills. Indeed, it was stated by at least one sanitary engineer, in an address before a convention of Sewage Plant Superintendents, that in the design of the Imhoff tank a totally satisfactory method of treating sewage had been obtained. Those who have had to do with the operation of Imhoff tanks, mildly speaking, are skeptical of such an assertion.

Several series of investigations have been conducted in an endeavor to learn the cause of "foaming", or what measures will stop or prevent "foaming". These have been almost fruitless. One investigation seemed to indicate that when a tank was placed in operation in the autumn or winter the low temperature inhibited the growth of liquefying bacteria; the sludge became acid and resulted in "foaming". On the other hand plants placed in operation during the spring or early summer digested their sludge well before cold weather; the sludge was highly alkaline, sufficiently so to keep the digestive process going until warm weather again arrived. The number of plants considered in this investigation, however, was small, and mention of it is made merely to indicate how thoroughly the writer has gone into the operation of Imhoff tanks in an endeavor to secure uniformly satisfactory results.

There has never been sufficient co-operation between the designers and operators of sewage plants to obtain the best results. It would seem that the Army proved no exception. Having been interested from both angles, the writer will not comment further.

Early in the war, the writer was assigned to one of the Aviation Fields, where the garbage problem was handled by the duplicate can system. No garbage cans were ever taken into the kitchen; they were kept on a screen-covered fly-proof platform some distance from the kitchen door. The wagons came alongside the platform, loaded the full cans without removing the covers, and hauled them away (in this case 10 miles). The cans were emptied there, scalded and rinsed in boiling water, and returned the next day. The garbage was fed to hogs. The entire process was arranged for and inspected by the writer, who was Sanitary Inspector.

The paper was collected and delivered to the Quartermaster who looked after its baling and disposal. Although an incinerator was provided, it was not used.

Each kitchen was supplied with a grease-trap which was cleaned every morning, the grease being stored in barrels with fly-proof covers. The grease was afterward disposed of by the Quartermaster.

Mr. Perry.

The sewage treatment plant consisted of septic tanks, a contact bed, and final disinfection. The twin septic tanks were covered and had a capacity of about 8 hours' flow, but due to the fact that all the flow was during 16 hours of the day, actual storage was somewhat less than 6 hours when the plant was placed in operation. Scum accumulated rapidly and reduced this storage to half, resulting in a very inefficient arrangement.

The contact bed was dosed by a siphon, but the bed was very small and the dosing tank very large, which resulted in the bed becoming full before the dosing tank emptied; some of each dose, therefore, was only strained instead of aerated.

There was no final settling or chlorine contact tank; the effluent from the contact bed was dosed as it passed under the chlorinator house. The chlorinator was a Wallace and Tiernan Type "A" Manual Control machine which was designed for a uniform flow rather than a pulsating flow from a contact bed.

The population contributing to this plant was somewhat more than 1 000, within 10% of the estimated population. The daily per capita water consumption was approximately 140 gal., although four times that quantity was available and the sewage plant was certainly not designed for more than 40 gal. The sewage plant was poorly designed and indicated little or no knowledge of the water supply.

The writer apprehended operating difficulties when the plans were shown him by the Construction Engineer, and took the matter up with Washington immediately, but the design was never changed. Although the Construction Engineer had to build the plant in accordance with plans and instructions from Washington, he secured permission to use about 1 000 ft. of sewer pipe for an outfall line to carry the plant effluent far enough away to prevent a local nuisance. As this effluent flowed about five miles through an open ditch, with almost no dilution, before being discharged into the river, it is plain that some complaints would follow. There was no complaint, however, while the plant was under the writer's observation, but it is seen that operation difficulties were present in that:

1.—Insufficient sedimentation was obtained; the sludge was not digested and was hard to handle.

2.—The contact bed operated merely as a strainer (analysis indicated that it did no good whatever).

3.—The chlorinator and appurtenances were of the wrong type, resulting in inefficiency.

No relief was obtainable, and the operator was responsible for the quality of the effluent. This constitutes the writer's personal experience with army sewage plant operation in the United States. Although no complaints were filed in this case, the plant was far from efficient, a fault for which the operator was not responsible.

Mr. Perry.

The experiences of a single observer are far too narrow for general statements; a soldier sees only the details immediately before him, and never has an opportunity to obtain a knowledge of comprehensive plans or the difficulties under which the officer at Headquarters has to contend. If based entirely on personal experience and observation, the writer's opinion concerning the activities of the Construction Division would be entirely different from the fair estimate that has been made possible by Maj. Doten's paper. His experience was similar to hundreds of other officers and, no doubt, the information contained in this paper will throw a new light to some of the critics of the War Department.

Mr. Doten.

LEONARD S. DOTEN,* M. AM. SOC. C. E. (by letter).—The writer in his paper endeavored to give a brief but comprehensive outline of the work in sanitation which had been accomplished by the Construction Division of the Army covering the period of the war to December, 1918. Special effort was made to present the facts as clearly and concisely as possible, all references to details of office organization and personnel, structural details of design, and other more or less extraneous matter having been purposely omitted. It is felt that too frequently the technical elements of papers on engineering subjects are subordinated to those savoring of commercialism, and as a result the factors of real value in the advancement of engineering practice are often obscured.

It is very gratifying that so many engineers have responded to the invitation to discuss this paper. In the writer's estimation these discussions in most cases have effectually supplemented the paper and are in themselves valuable contributions to the literature on sanitation.

After reviewing these discussions it is evident that most interest has been shown in the subject of sewage treatment. It had been anticipated that a more general discussion would be brought out on all topics, including collection, classification, and disposal of solid wastes, garbage can-washing equipment, and incinerators, as all these are important features in present-day sanitation work and will be of greater importance in the years to come.

As many requests, both verbal and written, have been received for data on results of operation of sewage treatment plants, and for information as to the best methods of operation, they will be complied with quite fully in this discussion. Furthermore, in order to correct a false impression which prevails to a certain extent, the writer takes this opportunity to state that neither the tank designs nor any other sanitary devices illustrated or described in the paper are patented.

The sewage tanks are so different in design from the European types, Cameron and Imhoff, which have been so commonly adopted for use in the United States, it is not strange that engineers unfamiliar with their development and having made only a superficial inspection

* Washington, D. C.

Mr. Doten. of some of the earlier plants at the camps, should not readily appreciate the advantages of certain details of design.

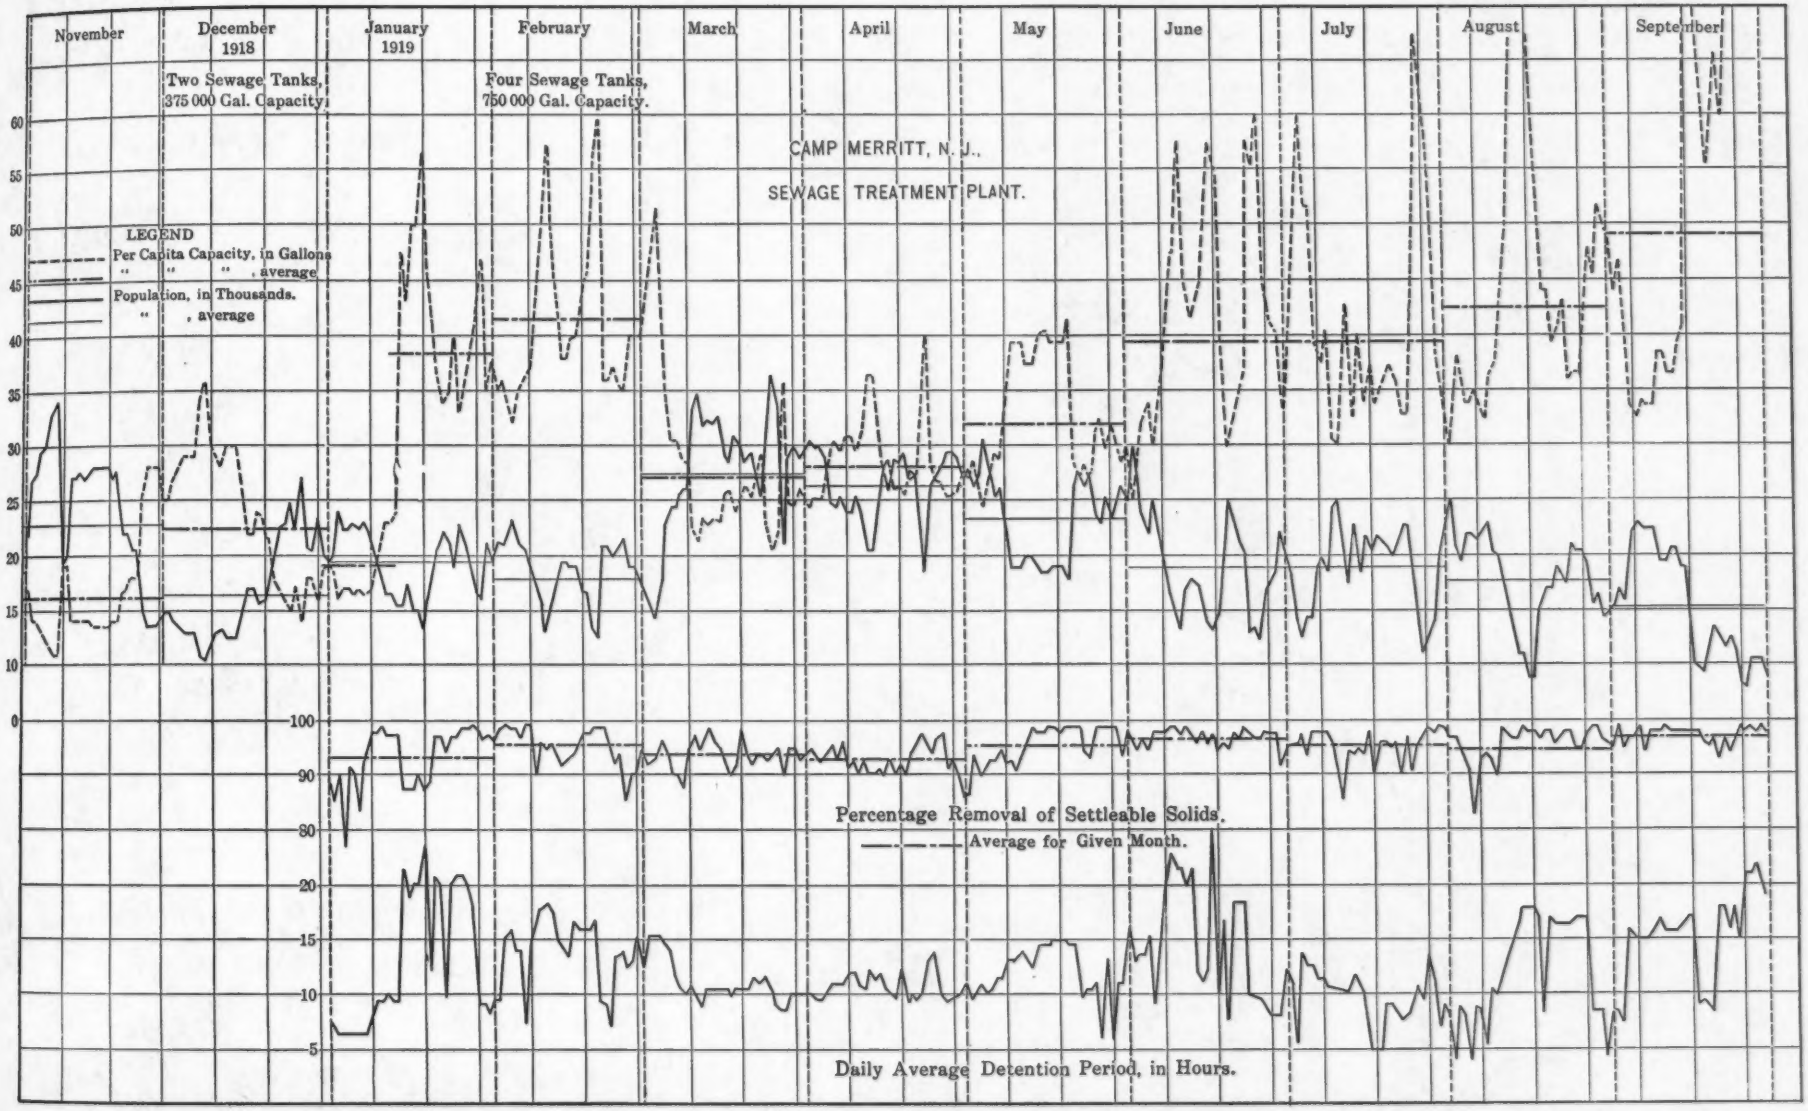
The adherents of the Imhoff principle were quite prone to use the term "sedimentation" in referring to the tanks, and were disinclined to acknowledge any evidence showing that they were not only "sedimentation" but also "digestion" tanks. Although opinion in regard to this matter has radically changed, yet it is probable that a few are still unwilling to admit the dual capacity of the tanks. It is evident from their discussions that Mr. Metcalf, Mr. Hill, and Mr. Fales are members of the first-named class. The writer's position on this question was clearly stated in his paper. It is a fact readily substantiated that to-day all the tanks are operated as digestion tanks and are functioning successfully.

Mr. Metcalf seems to have been misinformed as to the meaning of the instructions in the 1917 general specifications relative to requirements for capacities of tanks. The gross holding capacity was obtained by multiplying the number representing the maximum population of a camp, as determined by the rated capacity of the barracks and quarters, by 10 gal. The maximum population was used and not an average. It was assumed that the population would fluctuate widely. The large populations, in numerous instances greatly in excess of the rated housing capacity of the camps, and the continuous occupancy of the camps during the first eight to ten months, were the result of inadequate transport service due to lack of ships. During the latter part of 1918 this condition did not generally obtain, and the camp populations fluctuated much as had been anticipated in the early days of the war.

Mr. Hill's discussion of certain points relating to tank and grease-trap characteristics is so admirably frank that the writer feels there is a certain degree of impropriety in controverting his statements by using data obtained from the plant at Camp Merritt, where he was one of the supervising engineers during construction. The records of operation at this camp, however, are more complete than at the other camps, for which fact we are greatly indebted to Capt. Paul Molitor, the officer in charge of the plant, and, consequently, most valuable not only as an answer to Mr. Hill's criticisms, but to engineers interested in the study of sewage treatment processes. Although the results obtained at the Camp Merritt plant are not superior to those at many of the other plants, on account of the completeness and length of period over which the records extend, it was concluded to present the data in graphical form. Attention is invited to Plate VI. Furthermore, it may be of interest to Mr. Hill to learn that 221 756 lb. of grease in the aggregate was reclaimed at Camp Merritt from the kitchen traps. The following quotation is taken from one of the monthly reports:

"All grease traps were inspected four times during the month and scraped and the grease removed * * *, a total of 19 542 lb. being obtained, which was sold by the Salvage Department for $781.68."

PLATE VI.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXXIII, No. 1432.
DOTEN ON
SEWAGE AND WASTES DISPOSAL.



Mr. Doten.

By a careful inspection of the chart, Plate VI, and from the quoted paragraphs from reports on operation, it will be noted that the following are significant facts: (*a*) uniformly high percentage of removal of settleable solids, irrespective of season and rate of sewage flow; (*b*) rapid fluctuation in rate of flow and population; (*c*) digestion in tanks going on satisfactorily throughout the whole period; (*d*) very little odor about the plant; (*e*) effluent at all times in readily oxidizable condition; (*f*) all tanks were operating in parallel. The effluent was treated with liquid chlorine and discharged into a small tidal stream without creating any nuisance. In this connection, attention is called to the quotation from Capt. Molitor's report for September, 1919, which is given on page 381 of Mr. Sherman's discussion.

The following data are from reports on operation:

Camp Eustis, Va., August, 1919.—"Average daily sewage flow, 732 580 gal." * * * "All units of sewage disposal plant are in operation * * *. Sewage tank operation for month of August was satisfactory. 1 429 cu. ft. of sludge were removed on August 18th, from bays No. 2-A and No. 1-A. Sludge was dried out in a period of five days and carted away to farm."

From other reports received it has been learned that no scum forms on the sewage in these tanks, and that thoroughly digested sludge was produced in about six weeks from the time they were first put into use.

Camp Eustis, Va., September, 1919.—The following statement is contained in the monthly report prepared by the Sanitary Engineer at the camp and submitted to the Surgeon General of the Army: "The sludge was well digested and contained about 87% water." Similar reports have been received in monthly reports since that date.

Camp Merritt, N. J., July, 1919.—"Average daily sewage flow, 1 789 000 gal." * * * "The four tanks have been in operation during the month and are functioning in a normal and satisfactory manner, both as to clarification and sludge digestion. The sludge drawn from these tanks during the month was of good quality, well digested, very dark in color, and practically odorless, with the exception of a slight tar or burnt rubber odor, which is characteristic of thoroughly digested sewage sludge. The dry sludge is being carted away by farmers to be used as fertilizer. Weather conditions being favorable, this sludge would dry to forkable condition in from five to seven days."

Camp Sherman, Ohio, April, 1919.—"The new screens and grit chambers are operating satisfactorily and likewise the new sludge beds. The sludge is so thoroughly treated and dried that it is practically impossible to detect any odor whatever in the residual."

Fort Myer, Va., September, 1918.—The report of Dr. W. W. Skinner and Mr. J. W. Sale states:

"The sludge that is removed from the septic tank is disposed of by burying. It is not offensive, when dry, having only a slightly musty odor. The appearance and odor of this material, therefore, could not indicate its origin to the uninitiated."

Mr. Doten.

Camp Upton, N. Y., January, 1920.—The following endorsement was received from the Utilities Officer at this camp:

"Returned, with the information that we have experienced no difficulty in the operation of the sewage plant, except the normal one of developing new tanks and new sprinkling filter to the point of maximum efficiency, and that through our experience of the past seven months we have arrived at practically the same methods as are described in recent 'Instructions Relative to the Operation and Maintenance of Sewage Treatment Plants', dated at Washington, December 1st, 1919. We have brought our practice into line with these instructions where they differed in any details. * * *"

The stability of effluent from the trickling filter for the preceding month was given as 99 per cent.

The significance of the preceding statements is apparent to those engaged in the design of the plants. A misconception on the part of the earlier plant operators and their advisers as to the fundamental principles involved in the processes caused great delay in establishing effective and efficient methods. Since the stress of war conditions has passed somewhat, the writer has succeeded in bringing about more uniform methods of operation. A complete revision of the rules for the operation of sewage treatment plants was made in August, 1919. The following quoted paragraphs are taken from the revised operating instructions:

"*4.—Sewage Tanks.*—It is desirable to maintain an equal rate of flow through all tanks in service. To accomplish this, in certain cases it may be necessary to adjust the valves on inlet pipe lines or gates in distribution chambers. A uniform depth of flow over the effluent weirs of all tanks in service is an indication of proper distribution of flow in the several tanks.

"*5.—Number of Tanks to be Used.*—Where two or more tanks are provided, the operator shall use at one time such number of tanks as will provide an average detention period of not less than six hours nor more than twelve hours. In computing the detention period the entire capacity of each tank should be used.

* * * * * * *

"*8.*—During the first few months of operation it is essential to break up the scum daily by means of a hose stream or by aid of some mechanical device in order to avoid the formation of a heavy scum.

"When the bacterial development in the tank, especially the first compartment, has reached a certain stage, hosing is required less frequently.

"Scum formation varies considerably in different tanks, being dependent upon certain characteristics of the sewage. The important feature, not to be neglected in any particular, is the necessity of preventing the formation of a dense thick mass of scum.

"*9.—Lime Treatment for Acid Sewage.*—Wherever the litmus test shows an acid reaction in the raw sewage, milk of lime should be added in quantity sufficient to neutralize this acidity. The quantity of lime

Mr. Doten.

required will vary from 100 lb. to 500 lb. per million gallons, depending upon the degree of acidity of the sewage.

"*10.—Transfer of Sludge.*—At times it may become necessary to transfer partially digested sludge from the first compartment of a tank to succeeding compartments, in order to facilitate digestion. This is especially important where tanks are being used to their maximum capacity. The transfer may be accomplished either by means of a gasoline-operated diaphragm pump, or by drawing down the liquid in the last compartments through the draw-down valves and then transferring sludge through the sludge lines.

"Where the sludge pipe system is provided with a direct connection with a water distributing system it is desirable to agitate the sludge in the bottom of the first two compartments by the introduction of water through the sludge lines. This should be done in five-minute periods, weekly.

"*11.—Drawing of Sludge.*—Sludge should be drawn only when thoroughly digested. Sludge in the last compartment should be removed frequently in order to obtain an effluent low in turbidity.

"Sludge shall be drawn into sludge beds to a depth of not more than 12 in., after which sludge lines shall be drained or filled with water, or clarified sewage, to avoid formation of heavy deposits. Digested sludge should dry to a spadeable condition in 3 to 6 days, according to weather conditions. When sufficiently dried, the sludge should be removed from the beds and deposited in fills or disposed of as fertilizer.

* * * * * * *

"*Operators' Records.—19.*—Daily records should be kept of the amount of sewage treated; the maximum and minimum flow; the temperature of the sewage; the amount of rainfall; the quantity of screenings and detritus removed; quantity of disinfectant used; the quantity of sludge drawn on to the beds and dried; the results of the tests above outlined; and of the methods and cost of rectifying any unusual conditions arising in the operation of the plant."

In regard to Mr. Fales' reference to three standards of efficiency for sewage tanks, the writer desires to state that all three requirements have been fully met by the tanks under consideration, as shown by results of operation during the past two years. Mr. Fales' observations were largely made previous to the installation of grease-recovery tanks. Consequently, he did not have the advantage of observing the satisfactory operating conditions which followed. In this connection, attention is called to the fact that the original sewage treatment plant at Camp Dix, N. J., was constructed in accordance with plans prepared by the firm of which Mr. Fales is a member. It differed in several important details from the standard plans of the Construction Division. During the latter part of 1918 this plant was considerably enlarged by the addition of tanks and filters of the 1918 standard Construction Division types. This, with one other exception, is the only plant that was enlarged to the extent referred to by Mr. Fales as having been recommended by the Consulting Engineers. In both places trouble was

Mr. Doten.

experienced in operation on account of the acidity of the sewage resulting from low alkalinity in the water. This condition has since been overcome and the plants are now in exceptionally fine operating condition. Grease traps installed at the kitchens at Camp Dix have intercepted 362 000 lb. of grease, which has been sold for $18 000. More than 180 tons of grease therefore was kept out of the sewage tanks.

The plant at Camp Dix, as also that at Fort Sheridan, presents an interesting object lesson on the effect of baffling in single-story tanks. The old tanks at the former plant were constructed of wood and contained simply a narrow scum board at the outlet end of each tank. The new tanks have the standard type of baffling and sludge dams, shown in Plate V, except that the baffles are constructed of wood instead of concrete. It was found to be impossible at times to maintain the trickling filter in serviceable condition when the old tanks were in service, due to grease and the carrying over of gross suspended particles. On the other hand, the new tanks with even shorter detention periods yield an excellent effluent. The nozzles in the old filter at Fort Sheridan became clogged in a very short time when the old hydrolytic tanks were temporarily placed in service, but the new tanks with about the same detention period remove from 96 to 100% of all settleable solids.

The Fort Sheridan plant has been in service one year, and has been heavily loaded continuously during that period. As further proof that there are no gross particles of suspended matter passing from the new tanks, it is found that the two fine-mesh screens located in the effluent flume, shown in Plate V, intercept negligible quantities of such matter. These screens have $\frac{3}{16}$-in. openings.

As Mr. Allen's discussion deals wholly with the type of tank which was adopted by another Government Department, no comment will be made except to state that the Great Lakes Naval Training Station plant was not functioning satisfactorily at the time the writer inspected it in July, 1918, the aerating flume and rapid sand filter then being out of service. It is much regretted that Mr. Allen did not see fit to discuss the type of plant referred to in the paper, but it is assumed that his reluctance to do so was the result of lack of experience with the camp plant installations.

Mr. Kershaw's discussion is very interesting. The comparison of the test data on British camp sewage presented by him with the results of tests obtained in camps in this country, shows that the sewage in the latter camps was much more concentrated and that the quantity of suspended matter was much greater. The extremely high organic suspended matter content of the camp sewages was one of the surprising factors of the sewage treatment problem.

Mr. Doten.

Judging from the description of the typical sewage treatment plant adopted by the British Government, it is concluded that the cost per capita for such plants, if they had been constructed in this country, would have greatly exceeded the cost of the plants which were built by the Construction Division.

When it was learned that the Housing Department of the United States Shipping Board had adopted the design of plant described in the paper as its standard, the writer considered it a distinct compliment to the Construction Division, and especially later when it became known that this decision had been reached as the result of Mr. Hammond's recommendation after making a thorough inspection of a number of the War Department sewage treatment plants. It was reassuring to find that an engineer of such broad experience, who had gone deeply into the problem, had reached conclusions very similar to those arrived at by the writer. Mr. Hammond's discussion merits careful consideration by all engineers interested in this subject and should prove of great value in the advancement of engineering practice in sewage treatment.

Mr. Besselievre has stated clearly the advantages resulting from close supervision of sewage treatment plants by the designing engineer. It is so obviously the correct method to adopt that it does not seem to the writer to be a debatable question.

It is usually possible to improve the grounds about a plant at small cost so as to make them attractive landscape features. This should be done wherever practicable, as it stimulates pride in the plant on the part of the plant operator and municipal authorities and thus insures proper attention to details of operation and, consequently, satisfactory results unless the plant design is grossly at fault.

In order to secure the best results with trickling filters, designers should be careful to observe the points relative to details of design of dosing tanks and distributing pipe systems brought out in Mr. Besselievre's discussion. The advantages of such designs may be seen at many of the camp plants. The new filters at Fort Sheridan, Ill., and Camp Dix, N. J., are good illustrations.

The writer unintentionally omitted in his paper to state that the design of tank shown in Plate V was not typical of the earlier designs. Capt. Brown's reference to that fact, therefore, is appreciated. The design illustrated in Plate V is one of the last designs prepared in the Construction Division previous to the presentation of the paper, and was included among the other illustrations to show the latest practice. The design referred to by Capt. Brown as typical of the earlier practice is illustrated in *Engineering News-Record*, of November 15th, 1917.

The inclined baffle at the outlet end of the tanks was used early in 1918, but the inclined baffle at the inlet end was not used until the latter part of the same year. Both features, together with the sump

Mr. Doten.

in the bottom of each compartment, are included in the present standard plans, as will be seen by reference to Plate VII.

Capt. Brown's intimate knowledge of the details of design and principles of operation is evidenced by the excellent description which he has given of the action which takes place in the several compartments of the multiple-compartment sewage tanks. He also clearly describes the conditions at some of the camps previous to the installation of effective grease traps and to the organization of the operating forces.

Mr. Perry's conclusion, as well as that of Mr. Metcalf, relative to the difficulties which might be anticipated in the withdrawal of sludge from the compartments with pyramidal bottoms, is not confirmed by experience in the operation of the tanks. The sludge is readily drawn from the tanks without interrupting their use; it simply requires the opening of a valve. Rarely is it necessary to de-water a compartment to remove sludge. The writer has not learned of an instance of this kind during the past 1½ years, or since the early days of camp occupation, when due to misuse of the collecting system or to lack of proper attention to operation, the sludge withdrawal pipes became clogged with old clothing, large quantities of raw vegetables, or sand and gravel.

If designers in the past had devoted as much study to the design of tanks to meet the exact requirements of each individual problem as they have in their endeavor to fathom the mysteries of Imhoff tanks, their efforts would have met with much greater success. This statement is prompted by the expressions contained in the following quotation from Mr. Perry's interesting discussion:

"The writer cannot refrain from expressing his commendation to Maj. Doten for not adopting some form of the Imhoff tank as a standard of the Construction Division. Due to certain propaganda, almost all the laity and a large percentage of engineers regard the Imhoff tank as a panacea for all sewage ills. Indeed, it was stated by at least one sanitary engineer, in an address to a convention of Sewage Plant Superintendents, that in the design of the Imhoff tank a totally satisfactory method of treating sewage had been obtained. Those who have had to do with the operation of Imhoff tanks, mildly speaking, are skeptical of such an assertion."

The last portion of Mr. Perry's discussion apparently relates to conditions at one of the aviation fields with which neither the Construction Division nor the writer had any official connection. It is regretted that Mr. Perry did not bring out this fact more clearly.

Experimental Work.—This paper would be incomplete without at least a brief review of the experimental work and tests made at several of the sewage treatment plants. In April, 1918, Capt. E. J. Tucker and Lieut. J. J. Newman, Sanitary Corps Officers on the Staff of the Surgeon General of the Army, carried out a series of tests on the camp sewage treatment plant at Fort Myer, Va. In May of the same year

Scale

similar tests were carried out at the Camp Meade plant. Each of these tests covered a period of seven days. Samples of the raw sewage, tank effluent, and filter effluent, were taken at the Fort Myer plant at 15-min. intervals. The work was carefully carried out, proper allowance being made for the variable rates of flow in weighting results of analyses. As a result of this investigation Capt. Tucker arrived at the following conclusions: Mr. Doten.

"(*a*) The sewage at the cantonments is strong and concentrated, more comparable to that produced in European cities than to our American cities.

"(*b*) The sewage is delivered to the treatment plant at widely fluctuating rates, but due to the routine activities of the camps the periods of maximum and minimum flow occur at practically the same time daily. The maximum rate is about twice the average rate and the minimum is less than one-fourth the average. Knowledge of the daily flow and the variations in flow is of the greatest importance since it determines the design of the sewage treatment plant.

"(*c*) The sewage contains an abnormal quantity of grease which should be recovered both on account of its economic value and because it hinders the bacterial activities so essential to the digestion of solids in the sewage treatment tank."

The average grease content as determined by the series of tests at Fort Myer was approximately 115 parts per million. The tank removed 71% of the total suspended matter, 72.5% of the volatile suspended solids, and 77.6% of the fixed suspended solids. No determinations were made with conical glasses to obtain the percentage of reduction of settleable solids. It was found that the crude sewage contained an average of 717 parts per million of volatile solids and 500 parts per million of volatile suspended solids. The conclusion was reached that "allowing for variations in flow, accumulation of solids, and digestion of solids, it would appear that 20 gal. per capita should be the least that should be considered in arriving at the size of the tanks for the various cantonments."

In June, 1918, following these tests, effective grease traps were installed at all the company kitchens in the camp at Fort Myer, Va. The effect of the removal of large quantities of grease from the kitchen waste water was very noticeable in the improvement which took place in the sewage treatment plant.

Following the installation of these traps, Capt. Tucker carried out an interesting series of experiments to determine the efficiency of the traps. The report is too voluminous to be incorporated in this discussion, but the following are some of the conclusions reached:

"Therefore a unit capacity of 0.5 gal. per capita is ample size for any grease trap.

"The attached curves show the efficiency of grease removal of a trap of 115 gal. capacity, with respect to rate of flow in gallons per hour

Mr. Doten.

and temperature of the effluent. The conclusions to be drawn from these curves are that: (*a*) Efficiency is not reduced appreciably with ordinary flows which vary from 50 to 150 gal. per hour, and there is considerable loss in efficiency when rates are above 150 gal. per hour—in other words, when the flow per hour is less than or slightly more than the capacity of the trap, a good grease removal can be expected; at rates per hour 100 to 200% higher than the capacity of the trap there is a marked reduction in efficiency; (*b*) temperature of effluent has but slight effect except when accompanied by high rates of flow."

From the results of these tests and others that were carried out under the direction of Mr. A. B. Dunning, of the Construction Division, at Fort Myer and Camp Meigs, the conclusion was drawn by the writer that a grease trap suitable for camp use should have a capacity of about $\frac{3}{4}$ gal. per capita; that it should be designed so that the settleable matter would not be retained in the trap; that it was very important to keep the velocities in the traps as low as possible; and that the cooling of the liquid was of less importance than the control of currents. These ideas, together with the large liquid surface area for the collection of the grease scum, were the most important factors entering into the design of the trap adopted by the Construction Division as a standard.

The examination of the sewage at Camp Meade, which was made by Lieut. Newman, in May, 1917, confirmed to a large degree the conclusions previously reached at Fort Myer relative to the camp sewage characteristics. It was found, however, that the grease content at Camp Meade was considerably higher than that at Fort Myer, averaging about 154 parts per million.

The experimental work carried out at Fort Myer and Camp Meade in April and May, 1917, by Capt. Tucker and Lieut. Newman, was of much value in determining the characteristics of camp sewage and in bringing about better operation of plants.

A series of tests to determine the characteristics of the raw sewage and the efficiency of the tanks in the removal of suspended matter was carried out at Camp Custer, Mich., by Capt. C. B. Hoover, of the Construction Division, and Capt. F. E. Daniels, of the Sanitary Corps, in the fall of 1918. The tests began on August 9th and terminated on November 15th, and were made before grease traps of the improved type were installed. From these tests it was found that the average total suspended matter in the raw sewage was 594 parts per million, and the average volatile suspended matter was 476 parts per million. These results were obtained from continuous records covering a period of 43 days. The water consumption during that period averaged 42 gal. per capita. The results of the tests checked closely with the earlier tests at Fort Myer.

In September, 1918, a chemical and bacteriological examination of tank and trickling filter effluents was carried out by Dr. W. W. Skinner

and Mr. J. W. Sale, of the Bureau of Chemistry, Department of Agriculture. This investigation covered the period from September 18th to the 24th, inclusive. The following are brief extracts from the interesting report submitted by them as a result of that investigation. More complete data are given in a paper recently prepared by them and read before the American Chemical Society, at St. Louis, Mo., on April 15th, 1920. Mr. Doten.

"Data from the Boston and Reading plants are given for comparison:

	Septic effluent, parts per million.		Average.	
Total organic nitrogen...	4.7	Boston, 1907...	3.1	Fort Myer
Free ammonia.....	18.7	" " ...	19.0	"
Nitrite	0.0	" " ...	0.0	"
Nitrate	0.0	" " ...	0.0	"
Oxygen required.....	26.0	Reading, 1909.	32.0	"

	Trickling filter effluent, parts per million.		Average.		
Total organic nitrogen...	3.4	Boston, 1907...	0.7	Fort Myer,	1918
Free ammonia.....	12.0	" " ...	1.8	"	"
Nitrite	0.8	" " ...	0.4	"	"
Nitrate	5.3	" " ...	25.7	"	"
Oxygen required.....	..	" " ...	6.0	"	"

"A study of the data tabulated above shows that greater nitrification is effected at Fort Myer than at Boston. The reduction in total organic nitrogen and free ammonia, and the increase in nitrate in the trickling filter effluent at Fort Myer are of greater magnitude than those obtained at Boston. The low free ammonia figure and the high nitrate figure in the Fort Myer trickling filter effluent are significant and indicate that a very satisfactory oxidation was taking place at the period of observation."

No extensive chemical or bacteriological work has been undertaken recently at any of the treatment plants. The monthly reports contain the following data: Total flow in million gallons per day; maximum and minimum rates of flow per 24 hours; amount of precipitation each day; temperature of sewage at inlet to plant; quantity of screenings and detritus removed; a daily statement as to the number of tanks in service; settleable solids (2-hour periods, cubic centimeters per liter) in raw sewage, tank effluent and final effluent; the quantity of sludge removed, in cubic yards; condition of filter beds; relative stability of the raw sewage and final effluent; and details relative to use of chlorine, etc. From these reports Table 1 has been compiled to show the results obtained in sedimentation and stability of filter effluents.

Table 2, from "Sewage Treatment", by Messrs. Kinnicutt, Winslow, and Pratt, page 164, is inserted here for the purpose of comparing the sedimentation capacities of the multiple-compartment sewage tanks and the Cameron septic tanks. Although the data given in Tables 1 and 2 are not directly comparable on account of the fact that the de-

terminations have not a common basis, nevertheless, it is quite evident from a study of these tables that there is a great advantage to be derived from sludge dams and baffles such as are used in the former tanks. Mr. Doten.

* Suspended matter to nearest 5 parts below 100 and to nearest 10 parts above 100.

It is the writer's opinion that the importance of baffles in sewage tanks has not generally been fully appreciated by engineers. The results of tests covering long periods demonstrate conclusively that the baffled tanks provided with sludge removal pipe lines are much more efficient in sedimentation than the rectangular tanks, which are simply provided with one or two scum boards, and are not equipped with apparatus for the removal of sludge from the outlet end. In this connection the following quotation from Mr. Arthur J. Martin's recent inaugural address as President of the Association of Managers of Sewage Disposal Works in England, is especially interesting and significant:

"More pains might with advantage be taken to free a tank effluent from suspended matter before filtration. In a septic tank the partially digested sludge accumulates at the outlet end and as decomposition proceeds gives off a great deal of gas which breaks up the deposit and brings large quantities of it to the surface, where it is carried over with the effluent. This fouling of the effluent would not occur if outlets for sludge were provided at the outlet end of the tank and regularly used. By following precipitation tank practice one frequently finds the sludge valves placed at the inlet end."

Mr. Doten.

The data contained in Table 1 indicate that 5-ft. filter beds yield effluents of excellent quality. This would not be the result if the long period of dosing so commonly used in the design of municipal plants had been adopted. The humus from these filters is generally free from putrescible matter. In consequence, there is little gas disturbance in the secondary sedimentation tanks, with the result that the effluent is exceptionally free from suspended matter. The humus dries readily on drying beds and without odor.

Deep trickling filters, on the other hand, often produce humus which is decidedly putrescible and is objectionable on account of the bad odors which develop during the drying process. The odor factor is undoubtedly due to a large extent to the presence of decaying worms and other organisms which are deposited in the secondary sedimentation tanks. This condition is especially noticeable at the Fitchburg, Mass., plant, where the filters are 10 ft. in depth.

It is the writer's opinion that in future practice the local requirements as to degree of purification should be more carefully taken into consideration in designing the secondary treatment works. There are all gradations of such requirements, varying from the quality of a good tank effluent to that of the best possible effluent from a trickling filter or from the activated sludge process. It does not seem to be consistent, therefore, to install filters of the maximum capacity for oxidation and nitrification where a slight degree of purification would meet the requirements. As an illustration, a coarse rock filter, 3 ft. in depth, operating at a high rate per acre, would yield an effluent in some cases sufficiently stable to meet the local demands.

Where conditions do not admit of the construction of trickling filters for use in the secondary treatment of sewage it is believed that future practice will include designs of plants which incorporate the best features of both types of plants, sewage tanks with trickling filters and the activated sludge process. The cost of treating the effluent from tanks by the activated sludge process would be much less than to treat the entire sewage by that method. Such a combination plant would also have the advantage of making it possible to pre-treat the raw sewage before its entrance into the digestion tanks, so as to eliminate foul odors from stale sewage. The difficult problem of dealing with the large quantity of sludge from the activated sludge process would also be solved. This matter has been given considerable study by the writer, and plans are now under preparation for developing a plant of this type, in order to deal with problems where such conditions as limited area, proximity to habitations, and high degree of purification are controlling factors. However, the writer wishes it to be distinctly understood that he considers the tank and trickling filter treatment of sewage the most practical and efficient method for general use at the present time. It is only by the adoption of the best elements

and the elimination of the impracticable features that practice in this field of engineering may be brought to a high degree of perfection and standardization. Cost of construction would then be lower and operation more uniform and efficient. Mr. Doten.

The problems in sanitation dealt with during the war by the writer have been very interesting. In this work he has been ably assisted by engineers of broad experience and by those having special qualifications for the service. The writer refers particularly to the following engineers whose services have been of exceptional value: J. F. Brown, E. B. Besselievre, and A. L. Sherman, Associate Members, Am. Soc. C. E., and Messrs. H. R. Abbott, R. P. Hough, R. M. Ingham, Edgar B. Kay, and R. M. Renwick.

AMERICAN SOCIETY OF CIVIL ENGINEERS

INSTITUTED 1852

TRANSACTIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

Paper No. 1433

ADDRESS AT THE ANNUAL MEETING JANUARY 15TH, 1919.

By Arthur N. Talbot, President, Am. Soc. C. E.

If the President's address had been given at an Annual Convention, as the Constitution prescribes, a theme of greater entertaining value might have been chosen, but at the Annual Meeting it seems fitting to review some of the happenings of the year and to discuss the outlook for the Society.

War Service.

The year has seen the nation engrossed in the great World War. As engineering and the engineer have played a vital part in war activities, it was to be expected that the membership of the Society would take an active and responsible part. The summary of the Society Membership serving in the armies and navies of the United States and its allies, as reported in the *Proceedings* of the Society, is indeed a glorious record. A grand total of 1 640, ranging from major-generals and rear-admirals down through to the ranks, with a very high percentage in the positions of great responsibility, tells a story of active patriotism. To this should be added the large number of members who, at a sacrifice of financial and home interests, have given up their time to governmental and war activities in a civilian capacity, and others who have taken responsibilities in war service in various ways. The response made by the engineer and the service he has given prove that he has attempted to do his part in full measure.

The achievements of the engineer in war activities here at home are greatly to his credit. The incomplete accounts of the work of the American engineer on the soil of France at points of debarkation, on lines of communication, and at the front present a wonderful story; and the award of the Distinguished Service Cross and the French Croix de Guerre to many of our members tells of their great valor on the field of battle. Nor can we forget the many who sacrificed their lives in this great struggle—their's will be bright stars in the flag of humanity. We rejoice that right has prevailed, even at a great cost of effort and of lives. We trust that the conditions of peace settlement will be a guaranty of the future rule of justice and democracy.

Membership.

Notwithstanding the distractions occasioned by the war and the call of engineers to army and government service at home and abroad, the growth of the Society has been about equal to the average of recent years. The total membership on December 31st, 1918, was 8 933. As has been the case each year for several years, the number of Juniors has decreased during the year, the transfers to higher grades and the losses by death, resignation, and dropping being greater than the accessions.

Although the growth of the Society has continued regularly for many years, it may be noted that the total membership is exceeded both by the American Institute of Electrical Engineers, with a membership of 9 668, and the American Society of Mechanical Engineers, with a membership of nearly 10 000. Rapid gains have been made by these two societies in recent years. It may be noted that some societies, including many local societies, have secured large increases through membership drives, while the policy of our Society has been, not to encourage membership campaigns, but, instead, to accept the smaller but steady and substantial growth which comes without solicitation, in the belief that this method gives character to the Society and is productive of its best development.

Financial Matters.

Although the expenditures properly chargeable to the work of 1918 are considerably less than the Society's income for the year, the treasury is low. There are a number of reasons for this. The cost of the alteration of the Fifty-seventh Street property has taken about

$18 000 in addition to money secured on the mortgage of the property. As there was no income from the property until late in the year, the interest on the mortgage was an added expense. The annual charge to the Society for space in the Engineering Societies Building, together with the Library assessment, amounts to about $10 000 more than corresponding expenses in the old location. Rising prices have also affected expenses. The remission of the annual dues of many members in war service reduced the income for the year. It will be recalled that although a balance was reported a year ago, the printing and binding of the *Transactions* for 1917 had not been paid for. Available funds had been used in completing the payment of the Society's share in the extension of the Engineering Societies Building, and this is the real cause of the deficit. Efforts have been made during the year to keep down expenditures and to restrain activities. In a general way it may be said that, leaving out of consideration the alteration of the old Society House, the income for the year has been about $14 000 more than the expenses, and that, if the bill for printing and binding the 1918 volume of *Transactions* is considered and the special funds taken into account, the deficit on January 1st may be called $20 000, counting the advance dues collected as income for 1918.

The Fifty-seventh Street Property.

It will be recalled that it was announced a year ago that the property of the Society at 220 West Fifty-seventh Street, which had been the home of the Society for twenty years, had been given over temporarily to the use of the New York Federal Food Board, without charge to the Food Administration, except for the cost of maintenance of the building. It seemed desirable to make the property a source of revenue, and this involved changing the building from a society house to a business building. The remodeling has gone on since August, a lease for a term of ten years has been executed, and the building is now occupied by a responsible business firm. It is expected that the net annual returns from this property will be in the neighborhood of $10 000, not counting renewals and depreciation. The property itself is estimated as worth upwards of $400 000, and there is an encumbrance of $200 000. The value of land in that part of New York City is said to be rising rapidly.

The Engineering Societies Building.

The Society has now occupied its quarters in the Engineering Societies Building for more than a year. The work rooms of the office force have been found convenient and satisfactory. The reading room has been maintained and made attractive for members. The Society Library was merged with the Engineering Societies Library, and the library facilities of members are in reality greatly enhanced. The Society contributed as its share of the cost of the enlargement of the Engineering Societies Building the sum of $262 500, the whole property now being estimated as having a value of $2 500 000. Removal to the Engineering Societies Building has brought new associations, and particularly a closer association with the other Founder Societies. From every side come expressions of approval and satisfaction. In joining quarters with the other societies it is felt that a forward step was taken in extending the influence of the Society and the profession of engineering. It is not too much to hope that the coming together in the one building will prove to be a forerunner of many mutual undertakings and of much co-ordinated and co-operative work, all helping in extending the influence and promoting the solidarity of the profession.

Meetings.

An effort has been made during the year to get away from the usual programme of engineering papers, and, as far as possible, to give at the semi-monthly meetings matters relating to war activities. A number of interesting talks and addresses were given by American engineers and army officers, as well as by British and French officers. Naturally, the proper conduct of a war imposes restrictions regarding giving publicity to war activities, and on this account important war developments of engineering interest were not available for the use of the Society. An important development in the conduct of the meetings of the Society was the creation of a New York Meetings Committee charged with the conduct of the second meeting of each month. This act gives resident members a responsibility and an opportunity to make this particular meeting of special interest to local members. It is hoped that the movement will prove to be of great significance to the Society. Because of the war the Annual Convention was again abandoned.

Publications.

With the progress of time the war has absorbed more and more of the energy of the country; this condition has been reflected in the Society's *Proceedings*. As a measure of economy, also, the publication of papers has been curtailed. Six papers only were printed in the first half of the year; only discussions of papers have been given in the last half. On the other hand, the space devoted to announcements, items, and reports has been increased, and an attempt has been made to include more and more items of interest to members. The *Transactions* for 1918 are in press and will be issued soon.

Special Committees.

War conditions are not favorable for technical committee work. Committee members have been engaged in a variety of war activities, and, with all the distractions of the year and the scarcity of assistants, it would not be strange if the reports indicate less than normal activity. With the return of peace conditions it may confidently be expected that the Society's activities through its special committees will assume proportions in keeping with the opportunities which this agency gives for advancing professional knowledge and improving the standing of the profession, which should mean an expansion of committee work.

American Engineering Standards Committee.

A matter of great possible significance is the formation of a permanent organization, known as the American Engineering Standards Committee, to carry on the important work of co-operating in engineering standardization throughout the entire field of engineering standardization. The organization has been formed by the following societies: The American Society of Civil Engineers, the American Institute of Mining Engineers, the American Society of Mechanical Engineers, the American Institute of Electrical Engineers, and the American Society for Testing Materials, with three representatives from each of these societies and from each of the following United States Departments: Commerce, War, and Navy. Other societies and bodies may be allowed to co-operate in the work, by becoming "co-operating societies", but are not to have representatives on the Standards Committee. The procedure for formulating standards is somewhat com-

plicated. Any interested organization may propose the development or revision of engineering standards in any engineering field, and, if the Standards Committee approves, it will designate one or more of the co-operating societies as sponsor or joint sponsors for the standard under consideration, and give the sponsor authority to organize a special committee, to be known as a sectional committee, to carry on the work. Sectional committees dealing with standards of a commercial character (specifications, shop practices, etc.) shall be made up of representatives of producers, consumers, and general interests. Special committees dealing with standards of a scientific or non-commercial character shall consist of persons specially qualified, without regard to affiliations. The special committees will report their recommendations to the sponsor, and the sponsor, on approval, to the main Standards Committee. The Standards Committee may then approve the proposed standard as "Recommended Practice" or as "Tentative Standard", and when, in the opinion of the Standards Committee, after approval by the sponsor, it has proved its suitability, the Standards Committee may constitute it an "American Standard."

It will be seen that the organization may deal with standards and specifications in the whole range of engineering: materials such as steel, timber, cement; articles such as beams and structural parts, rails and ties, water pipe, machine parts; methods of work such as road building, concrete making; governmental requirements such as building regulations, requirements for working stresses, regulations for fire-proofing; scientific standards, such as methods of testing, standard technology, requirements for water supply; and specifications and standards of hundreds of kinds. It thus offers great possibilities for usefulness, and there are sources of danger. It is also to be seen that the formation of this organization may take from the Society opportunities for independent action on some matters. If the American Society of Civil Engineers handles its part in this organization vigorously and wisely, it will prove an opportunity for service to the profession and the public. If it does not care to be active in the matter, the field will be taken by others.

Engineering Societies Employment Bureau.

On the initiative of the Board of Direction of the Society, an Engineering Societies Employment Bureau has been established by

United Engineering Society, with the Secretaries of the four Founder Societies as the Board of Managers. It is believed that this plan will prove helpful to members and to others.

United Engineering Society and Related Organizations.

The past year is the first full year in which the Society has participated in the co-operative activities of the Founder Societies, and it may be well, therefore, even if a repetition is made of information published elsewhere, to review briefly the organization and functions of United Engineering Society, Engineering Council, Engineering Foundation, and other related organizations of the Founder Societies. Since the Society is participating in the work of these organizations and has given over to them some functions formerly carried on within the Society, the activities of these organizations should be considered as part of the work of the Society. United Engineering Society is the central organization. The related organizations, such as Engineering Foundation, are established and maintained through or by the United Engineering Society. United Engineering Society, is the holding corporation for the real property; it holds the title to the Engineering Societies Building. United Engineering Society also holds the title to such trust funds as may be contributed for the special purposes of the related organizations. United Engineering Society maintains the building and determines the apportionment of the budget among the several Founder Societies and the associate societies which occupy space in the building. It may establish departments or related organizations. United Engineering Society is thus the business and co-operating corporation which acts for the four Founder Societies. The governing board is the Board of Trustees, which consists of twelve members, three being selected by each of the Founder Societies.

United Engineering Society maintains and conducts the joint engineering library through the Library Board of twenty-one members, composed of the Director of the Library, the Secretaries of the Founder Societies, and sixteen other members, four being designated by each Founder Society.

The department known as the Engineering Foundation was established for the furtherance of research in science and engineering and for the advancement in any other manner of the profession of engineering and the good of mankind. The control and administration are placed in

the Engineering Foundation Board which is composed of the President of United Engineering Society, *ex officio,* and the following members elected by United Engineering Society: one trustee of the United Engineering Society from each Founder Society, two members from each Founder Society, nominated by its governing board, and three members at large.

Engineering Council was established "* * * in order to provide for convenient co-operation between the four Founder Societies, for the proper consideration of questions of general interest to engineers and to the public and to provide the means for united activities of common concern to engineers. * * * The Council may speak authoritatively for all member societies on all public questions of a common interest or concern to engineers, unless objection be made by a majority of the representatives present of one of the Founder Societies or by one-fourth of the representatives present and voting," which is the phraseology of the By-Laws of United Engineering Society. It has been the general understanding that Engineering Council was formed to undertake, not the technical activities of professional societies, but rather the non-technical, semi-professional, and general work, and especially that which bears upon public interests and public affairs. At a recent meeting, Engineering Council, in an effort to define its field, declared by resolution as follows:

"That Engineering Council understands its fields of activity to be approximately as follows:

"(1) Council may deal with any matter of general interest for which joint action of two or more of its member societies would have been appropriate, if Council had not been established.

"(2) Council may initiate and carry through projects of the general character defined in the by-laws, for which the necessary financial provision has been made; but Council shall not undertake expenditures in excess of appropriations for its uses made by United Engineering Society on behalf of the Founder Societies and the contributions from other member societies, unless specific provision shall have been made therefor by subscription, donation or otherwise; moneys received by Engineering Council shall be turned into the treasury of United Engineering Society and disbursed by it, for the purposes designated.

"(3) Council may take up, and in its discretion act upon, any matter of general interest referred to it by any member society or by any other society—national, state or local—or by any branch of Government, or by an individual or group of individuals."

It further declared:

"Engineering Council will, as a rule, avoid considering any matter which is specifically within the province of only one member society and not of others."

It is evident that Engineering Council has broad powers and responsibilities in the co-operative field.

It may also be proper to make note of some of the activities and accomplishments of these organizations. As the addition to the Engineering Societies Building was completed in 1917, the work of United Engineering Society has been the maintenance of the Engineering Society Building and the carrying on of relations with the Founder Societies and the related organizations. At the beginning of 1918 an important change in organization was made by the engagement of a Permanent Secretary who also acts as Secretary of Engineering Foundation and Engineering Council. Alfred D. Flinn, M. Am. Soc. C. E., the Permanent Secretary, entered upon his duties on January 1st, 1918.

The Engineering Foundation was organized in 1916 when Mr. Ambrose Swasey, of Cleveland, Ohio, Past-President of the American Society of Mechanical Engineers, offered the United Engineering Society $200 000 as the nucleus of an endowment "for the furtherance of engineering, for the advancement of the profession and the good of mankind". This was a magnificent gift for a great cause—the advancement of engineering and the good of mankind. This eminent engineer, however, did not rest content with one contribution, but in September, 1918, he added $100 000 to the endowment, making the total $300 000. It is confidently expected that the good example set by Mr. Swasey will be followed by contributions from many other persons—engineers and others—including the smaller contributions from those who cannot give large sums, as well as princely gifts from those of large means.

The income from the present endowment, of course, would not permit the Engineering Foundation to undertake engineering research itself on any considerable scale, for the carrying out of the larger engineering research activities requires large sums for successful accomplishment, and the engineering field is very large and the problems are very numerous. The Engineering Foundation wisely decided to devote its main effort for the present to activities which would serve to

encourage, direct, and develop research agencies and activities, at the same time giving such aid to research work as is found practicable.

The possibility of the United States being drawn into the World War brought about, in the summer of 1916, the organization of the National Research Council, an organization of scientists, engineers, and educators. The Engineering Foundation saw the needs of the organization for funds, and contributed facilities and money until Government support became available for the work. Thus started, the organization became extremely helpful to the Government in the prosecution of the war. Finally, it became the Department of Science and Research of the Council of National Defense, and, by executive order of May 11th, 1918, it was permanently established in its useful work. The Engineering Foundation was very helpful at a critical time in thus assisting in an important movement for stimulating research, and thereby rendered the greatest possible service to the country at the time. With the co-operation of Engineering Foundation and the National Engineering Societies, the National Research Council early formed an engineering committee, which later became the Engineering Division and has the following aims:

"To carry out the general purpose of co-ordinating the scientific resources of the entire country as regards engineering and to secure the co-operation of all engineering agencies in which research facilities are available."

The Engineering Foundation and the American Society of Civil Engineers have representatives on the Engineering Division. The Engineering Foundation has continued to affiliate with the National Research Council in various ways, as, for example, in collecting information about the several hundred industrial research laboratories existing in this country and in helping to stimulate industrial research.

It would give a wrong impression if reference were not made to a number of instances of stimulation of research on special problems by small grants of money, such as for the investigation of the secret selective control of wireless communications, the wear of gears, weir measurements of water, and a proposed method of camouflaging vessels. Generally, however, Engineering Foundation is proceeding on the policy that its resources should be devoted to large enterprises and the solution of problems of broad application, rather than to detailed investigation of limited problems. The opportunities of Engineering

Foundation in helping in the advancement of engineering are abundant, for the advancement of the art of engineering is dependent on scientific research, and the standing of the engineering profession as a profession will be markedly affected by its attitude toward research.

Engineering Council has started out on important work. Considerable attention has been given, since its organization meeting on June 27th, 1917, in exploring its proper field of activity, in deliberating on what it may and may not undertake, and what it should and should not undertake—important questions for a body which is starting on undeveloped territory. At the same time, it has gone ahead with activities. Through the American Engineering Service, which it organized for war-time service, it rendered aid to the Government, resulting in procuring thousands of engineers for the war, navy, and other departments. Through the War Committee of Technical Societies, assistance was given the Naval Consulting Board and the Army General Staff in examining thousands of suggestions for naval and military devices. The names of the committees of Engineering Council at work indicate in some measure present or intended activities: Public Affairs, Fuel Conservation, Patents, Industrial Affairs, Water Conservation, for all of which progress is reported. At different times Engineering Council has been represented at Washington in respect to matters of interest to engineers, and its activities there have borne fruit. It is organizing a National Service Committee to give instant, active, and constant representation of engineers at Washington, especially on matters relating to reconstruction affairs. Engineering Council is endeavoring to keep in communication with communities of engineers all over the country. The preliminary work of organizing its activities has made considerable progress during the year. Engineering Council has an important task in attempting to provide for consideration of matters of common concern to the profession.

It will be agreed that the aims and functions of United Engineering Society and of these co-operative agencies are of far-reaching importance to the American Society of Civil Engineers and its membership. Their opportunities and responsibilities are indeed large.

The Award of the John Fritz Medal.

The profession of civil engineering has been recognized and honored through the awarding of the John Fritz Medal to a prominent and

distinguished member of the Society, J. Waldo Smith, for his most distinguished service in engineering and great achievement as engineer in providing the City of New York with a supply of water. The public presentation was made at a meeting which took the place of a regular meeting of the Society. It is worthy of note that, in the fourteen times the medal has been awarded, this is the second award for what in the narrower sense may be called strictly civil engineering achievement, the first recipient being the late Alfred Noble, Past-President, Am. Soc. C. E.

A Mission to France.

Responding to an invitation extended to the Society by the French Society of Engineers, with the approval of the French Ministries of Public Works, of Commerce, and of Armament, to send a small delegation of engineers to meet in joint engineering congress in Paris for the purpose of discussing technical matters relating to reconstruction work and the utilization of commercial ports, the development of navigable waterways, the development of water power, the improvement of road systems, and of other engineering and industrial interests of France, six representatives of the Society were chosen, who, with three representatives appointed by the other Founder Societies, sailed for France early in December, and are now engaged in sympathetic assistance in the consideration of important problems related to the future development of the resources and opportunities of our sister republic. The State Department sanctioned the going of the mission, in the belief that its presence in France would be taken as evidence of America's desire to make real the ideals that have triumphed in the war. The matter is significant, not only because it gives American engineers an opportunity to be of service to the engineers and people of France, but because of the opportunity it gave the Society to extend to the other National Societies an invitation to participate in a matter of general interest, an action which has been accepted by the other societies as an evidence of our desire to co-operate.

The Committee on Development.

At its June meeting, the Board of Direction took a step which it is hoped will have significant and far-reaching results in the development of the Society and in increasing the usefulness of the engineering profession—the creation of a committee to report on the purposes, field

of work, scope of activity and usefulness, organization, and methods of work of the American Society of Civil Engineers—the purport of the resolutions being amplified by the preamble. The method adopted for selecting the committee gives a wide geographical distribution and an opportunity for the representation of local views. The Committee on Development held its first meeting in Chicago in November, spending three days in the discussion of its work. The preliminary report of the committee has been sent out to the membership. Sub-committees are at work on the development of the subject, and doubtless they will find a large task ahead of them. To prepare a final report adequate to the problems set before the committee and worthy of so great a cause will take long hours of work, much thoughtful deliberation, and the highest constructive powers. Let us give our full support to the Committee on Development in its labors.

It is worthy of note that the three other Founder Societies have appointed committees to undertake the same kind of an inquiry.

The Work of an Engineering Society.

It would be presumptuous to attempt to forecast the outcome of the work of the Committee on Development. It seems proper, however, to try to bring to your attention this morning, in so far as the time will permit, some of the matters which appeal to me in studying what should be undertaken by the American Society of Civil Engineers.

What are the purposes and functions of an engineering society such as the American Society of Civil Engineers? In discussing this question, it is necessary not to restrict ourselves to the purposes given in the Constitution of the Society, which may merely follow precedent or may be worded to conform to a State statute governing the charter of the Society. Whatever may be our views of details, may it not be agreed that at least the following should be involved in a national engineering society:

A learned society; a collector and disseminator of engineering knowledge; a forum for the discussion of engineering questions, simple and complex, small and large; a stimulator of research and of the progress of engineering science; a developer of engineering methods and practice; an active force within and without professional circles; a creator of engineering policies and an originator and patron of constructive and progressive movements in engineering; an opportunity

for meeting and knowing the engineers of the country; a means of mutual helpfulness and co-operation for the profession and its clientele; an instrument for advancing both professional interest and public welfare; an agency for discussing the various phases of public problems and for participating in the service which all thinking organizations should give to society.

And the engineering society has justified its existence. It has helped to create the engineering profession. Its accomplishments, technical and extra-technical, all redound to its credit and to the credit of its membership. To recount the activities and achievements of the engineering society, within its walls and in service to the public and to society, in matters that are known to all, and in ways that are not usually recognized, would consume much more time than is available here. And the engineering society has given *esprit de corps* to the profession. It has made its members feel self-respecting. It has called to the attention of many the high standards held by the profession and the responsibility attached to membership in it. It has continuously raised the standards and the standing of the engineering profession, and has assisted in establishing this standing in the eyes of the public. The members who put the most into their membership relations get the greatest benefit, but the inactive member, perhaps unconsciously, profits by its beneficent influence, for there are intangible benefits and advantages which come from the presence and activity of the engineering society.

All this is accepted without argument in an audience such as this. The question up for consideration is what should be done to extend the usefulness of the engineering society and to make it a greater force for its membership, the profession, and the public.

Technical Activities.

The technical side of the activities of an engineering society is of prime importance. Engineering is and must continue to be a technical art, a technical business. Its body of technical matters is far larger and more important than existed a generation ago, and the requirements for technical knowledge in engineering work are increasingly important. By technical matters are meant more than mere mathematical methods and the routine work of engineering; all the relations to the science and art of engineering in and out of professional circles are included, and

also the technical features of the business side and the technical relations with the public. Important as is the administrative and executive side, the characteristic and determining feature of engineering is the technical side. The time is past when ingenuity, rule-of-thumb methods, and workmanlike skill alone will make an engineer. If engineering is to be only a combination of business and routine construction, it becomes a craft, a mere line of business. The engineering society should be a principal factor in the development of the science and art of engineering, in developing and recording the technical side of engineering, the scientific substructure, the overlying elements of practice, the variform connections with business life. By the technical side is here meant, not alone a knowledge of engineering principles and facts; it involves creating engineering policies, developing engineering practice, improving and controlling engineering connections with the outside business world. To carry out its technical functions properly is a high aim for an engineering society.

One of the methods of carrying on this technical activity has been through the presentation and discussion of papers and publications on engineering topics. The contributions of the Society in this direction have been of great importance. It would seem worth while, however, to raise the question whether the Society is doing all it should do in this direction. Is there not need for papers in fields not often taken up in the Society *Transactions*? Should there not be more short, terse papers, devoid of details, which should stimulate and set engineers to thinking? Would it not be possible and desirable to have more papers dealing with principles, with the advances of engineering, with new methods and requirements? May it not be worth considering whether we should hold to the long-used policy of limiting ourselves only to those papers which are offered to the Society from time to time, regardless of whether this policy leads to ignoring large fields and results in transferring to other societies and agencies activities in these lines; and, aside from papers, are there not opportunities for dissemination of knowledge which may properly be undertaken—like reviews of engineering construction and methods, digests of important engineering literature, which seem now not to have adequate expression through other agencies?

Work of Technical Committees.

Technical committees form one of the most effective means of carrying on the technical activities of an engineering society. Such

committees are able to utilize the experience and ability of many members and to take advantage of facilities and opportunities afforded by outside organizations. They can co-ordinate and unify practice, develop methods and recommend acceptable practice, acquire technical knowledge, formulate principles and standards, and recommend improvements and advances in the art. Their influence can reach out far beyond the bounds of the Society. Experience shows that committee work may be a power for good. Two of the specialized engineering societies of national character carry on the larger part of their work through committees. The American Railway Engineering Association has 23 technical committees, with a combined membership of 480 out of a total membership of 1 300 in the Association. The subjects for these committees range from ballast and rail to economics of railway operation and economics of railway labor. The American Society for Testing Materials has 38 technical committees and 144 sub-committees, with a combined membership of 1 094 out of a total membership of 2 300. Committee A-1 on Steel, which has had great responsibilities in the past few years, consists of 121 members. The membership of both of these societies gives a great amount of time and attention to committee work. The influence of the work of these two societies has gone out far beyond their membership, far beyond the limits which the names of the subjects would seem to make possible. At the risk of seeming disloyal, the opinion may be advanced that in influence on engineering practice, in effect in the industries, in influence on relations of engineering business, in advancement of engineering knowledge and the methods of manufacture and construction, and in influence in the outside business world, the achievements of these two specialized societies in the past few years have been such as to make some of the National Engineering Societies look to their laurels for leadership. It may not be too much to express the belief that the Committee on Development will find the need and opportunity for technical committee work an important subject for study.

Specialized Divisions or Sections of the Society.

What seems to be an opportunity for energized activities lies in the formation of specialized divisions or sections of the Society to give attention to special fields of work, such as railway engineering, structural engineering, and hydraulic engineering. Members would enroll in sections in which they are interested. Sessions and conventions

would be held to discuss matters of common interest. The railway engineering division might hold membership in and co-operate with the American Railway Engineering Association, giving attention to certain features of the convention and committee work of that society. Another division might affiliate in some way in the work of the American Society for Testing Materials—in fact there is an unoccupied field closely allied to the work of that society. A division interested in sanitary engineering might find a welcome with the American Public Health Association. The activities of such specialized divisions would reach outside the membership and give new points of contact and influence over the outside world. New forces would be set up among the membership, and new opportunities for participation given.

Formulation of Engineering Policies.

Both the committee work and the specialized divisions constitute effective agencies for creating engineering policies and originating constructive and progressive advances in engineering and related matters—important functions for an engineering society.

Local and Regional Organizations.

In any discussion of National Engineering Societies it must be borne in mind that the membership is scattered over the country; that there are numerous centers of engineering, and that these are yearly becoming more important; that local engineering societies in these centers are essential elements in the life of the engineering profession; that these local societies furnish a means by which the young and growing man meets and knows other engineers and gains opportunity for development; that the National Societies may be greatly strengthened and their influence extended by closer affiliation with these local societies, and that any thorough consideration of the subject of aims and organization should endeavor to find ways and means by which the National Society may best effect closer co-operation with the local engineering society. It is also true that local conditions vary greatly, from place to place, over the country, and that the problems and the methods of contact with the public are far from uniform.

In the last few years there have been formed twenty-two local associations of members of the American Society of Civil Engineers (a term which I hope will be replaced by a less clumsy one such as

Chapter) at centers of engineering over the country. These local associations, if cherished a little, may be expected to be very active elements in the life of the Society. They should also become important elements in the life of the communities in which they are.

In many of the centers of population the local engineering societies are well established; in others they will become so. It would seem wise, in any attempt at organization of the profession throughout the country, for all the National Societies to join forces with these local societies in every possible way. In every center of engineering the local engineering society should be the basis of organization. Some plan should be devised, perhaps by increase of dues, to contribute revenue from the treasury of the National Societies to the Chapters for use in this union work with the local societies. It is evident that closer connection with the local engineering societies will promote loyalty in the National Societies. I believe some form of organization may be worked out which will win the support of the tributary membership and greatly strengthen both National and Local Society.

For certain purposes it may be found desirable, also, to have a regional organization, covering territory corresponding to districts, like those of the geographical districts used in the selection of the Nominating Committee, for handling matters of common interest over a region, a matter which could be worked out in connection with the management of the local associations.

In dealing with our distributed membership, the situation in New York should not be overlooked. The provision for a New York Meetings Committee to take charge of the second meeting of each month, made by the Board of Direction on the recommendation of the Secretary, is a step in advance. It would appear to me that, in any new plan for local associations or regional organizations, the resident membership (those within fifty miles of the New York City Post Office) should be granted some degree of autonomy, by the formation of a local association or chapter or otherwise, and that the New York membership should be set at work and stirred up to realize and utilize the opportunities and facilities at their door.

Relations with Other Societies.

Intimately connected with the question of local associations and local societies is the question of our relation with other National

Societies. These relations are yearly becoming of greater import. The four Founder Societies have many activities in common. Engineering Council may soon have its membership increased by three more societies. The Engineering Standards Committee will have the co-operation of a number of societies, besides the four Founder Societies. The opportunities for co-operation are increasing. It is increasingly apparent that engineering is a single profession; the various branches ramify and merge into each other in numerous ways. Many engineers think there should be one large inclusive engineering society to take the place of the several National Societies—to be made up of the 35 000 engineers in the four Founder Societies or the 100 000 or 200 000 who may claim the right to be classed as engineers. It does not seem probable now that the immediate future will bring about such a single organization. In default of this desideratum, the best use possible must be made of existing agencies. Organization should be effected which will bring united effort along many lines. The further union of National Societies and their co-operation with the local societies of the engineering centers in developing engineering society activity are potential factors for the future. This, too, is a fruitful field for the Committee on Development.

Relation to Public Affairs.

It has frequently been remarked that the engineer is likely to be confined so closely to his own work that his influence does not extend out as far as it should, and particularly that he has not taken part in public affairs, in governmental and economic activities, to an extent warranted by his training and business standing; and, further, that the engineering society has not accepted in full measure its opportunity and its responsibility in public and civic matters. To recount the accomplishments of the engineer in civic affairs, in governmental activities, in influence on public policy, in the solution of industrial problems, would show a creditable record; and the engineering society likewise has achievements greatly to its credit; but, notwithstanding all these accomplishments, it must be apparent to all that the engineer and the engineering society now have opportunities and responsibilities in the direction of public duty far beyond what they have hitherto considered as their share. This is especially true at the present time, when the successful solution of so many public problems lies within the province of the engineer.

The consideration of quasi public matters has not always been accepted as a proper field for Society activity. As an illustration, the opposition to the creation of a Committee on Valuation of Public Utilities may be recalled. When the Board of Direction was discussing the measure, a member opposed it because he felt strongly that the engineer should confine himself to the design and construction of engineering works, and another because valuation was not an engineering question and should be left entirely to the Courts, overlooking the service which only the engineer could give in correlating the engineering data and establishing principles to be considered in making decisions. Fortunately, the advocates of the appointment of the committee prevailed, in the end, and a magnificent report and discussion was given to the public, a report and discussion which doubtless will continue to be used and quoted whenever and wherever the valuation of public utilities is discussed by layman or Court. Besides, the activities of the committee stimulated thought and provoked discussion throughout our membership as few subjects have done.

How the engineer and the engineering society may best deal with public matters is a complicated question. The engagements of most engineers are not like those of the lawyer. There is a great diversity of condition of service and environment, even in the same lines of engineering, and the interests are very diverse. Evidently, a satisfactory plan may be evolved only after much study, and only a few of the elements of the situation may be touched upon here.

Part of the public work of an engineering society lies in bringing to the attention of public bodies technical and other matters already available through its committees and its publications, and in giving co-operation along lines where general technical information and direction will be helpful. Civic improvement and city planning, health and sanitary conditions of cities and communities, industrial conditions and their betterment, the need of high-grade engineering supervision of public work, are examples in one direction only. The public should be taught that there is a great body of knowledge, experience, and expert judgment the utilization of which greatly benefits mankind.

Certain matters of public interest are frequently considered through independent or auxiliary organizations, more or less temporary in character. The agricultural interests use such agencies rather freely. The

Reconstruction Congress of War Service Committees is a recent activity, held under the auspices of the United States Chamber of Commerce, to recommend what American business ought to do for the Government and what the Government ought to do for American business. Waterway conventions and drainage congresses are also examples of this method of work. Unless savoring too much of propaganda and special interests, the method of disseminating information, stimulating discussion, and influencing public opinion through special organizations, is effective and legitimate.

Direct connection with Governmental agencies may be difficult. Special instruments may need to be created. Great credit should be given to Engineering Council for the start it has made in handling public matters in this first year of its organized activity. Its recent creation of a National Service Committee, with an appropriation for expenses, for active and constant representation of engineers at the seat of the National Government, in these times when reconstruction problems involving engineering are at the front, is a very promising movement. It illustrates the type of work which the engineering society can undertake. A variety of methods will have to be used. Those public problems which are local, or are confined to States or limited territory, may be handled most satisfactorily through local or regional organizations.

It would be premature to try to outline here methods for accomplishing the great work in public matters which should be undertaken, or the form of organization which is needed. The formation of a large and representative public affairs committee has been suggested, and also a delegate convention organized to discuss matters of public interest and intended as a forum for voicing the sentiments of the organization. More than these are needed. So much time has already been taken in this address that I will not attempt to outline my views. Whatever is done must give opportunity for exercising initiative and providing powers for action. Leaders must then energize the machinery provided.

Financial Considerations.

The activities here referred to will require adequate funds; it takes money to do things in this world. Our equity in the Engineering Societies Building, which seems a princely one, can never be a source of revenue, but must continue to be a large item of expense, however

much it adds to the standing and respectability of the Society. The present stringency in our treasury is believed to be temporary, and January, 1921, should begin with current expenses all paid and a balance in the treasury at least equal to the advance dues collected, together with such special funds as may have been contributed from outside sources.

It must be understood, however, that if the activities of the Society are to be extended, funds must be provided to pay the accompanying cost.

Part of this may well be taken from the annual balance of $20 000 or $30 000 which in normal years may be left after paying the expenses of present activities. It seems reasonable that a society which has become established financially should not continue to put aside from annual receipts very large sums as endowment; the increase in endowment may be expected to come from other sources.

Increase in membership will bring increased revenue beyond the accompanying expense. Many believe that there should be a considerable increase of membership.

With increased activities and higher costs for everything, it is possible that an increase in annual dues may be worthy of consideration.

The expense of some activities may be borne from contributions from various sources, probably a fruitful source of revenue for several lines of activity.

Much of the work which may be undertaken will be carried on by individuals and organizations—the Society's part will be to organize, stimulate, and direct.

If it is agreed that there are activities which the Society should undertake for the benefit of the profession and society, activities that will bring results and that will help in making the Society a force of greater and greater influence, who will doubt that resources will be found to finance the work?

Conclusion.

Altogether, it is a great problem—one worthy of the best thought of the Committee on Development and the Society. To shun the visionary, impracticable schemes, and yet be not too complacent about past accomplishment; to seek to be national and not provincial; to try to be both democratic and efficient; to lead in the progress of the times and

yet to hold to the old and proven good; to work to be a powerful engine in technical affairs and a vital force in the life of the profession; to learn how best to give service to the community and the nation; to provide methods by which the profession may lead in progressive movements—these are ideals worth striving for in making a plan. It should be borne in mind, too, that elaborate or complicated organization is likely to be ineffective; the machinery is not self-propelling. Mere paper proposals will not suffice. Whatever is done, we must keep down on earth, accept only workable plans, but still not be content with stagnation or mediocrity. It is my belief that a plan may be worked out befitting the needs of a great profession, and that, with such a great opportunity before it, the Committee on Development will evolve a plan satisfactory to the Society. The discussion of the whole question will serve to stimulate interest, improve spirit, and arouse latent vitality. May we not expect that the result will be a stronger, more useful, more virile Society? As members we confidently look forward to a great future for the American Society of Civil Engineers.

Paper No. 1434

THE PROPOSED NEW YORK AND NEW JERSEY VEHICULAR TUNNEL

AN INFORMAL DISCUSSION AT A MEETING OF THE SOCIETY, MARCH 19TH, 1919.

BY MESSRS. EDWARD A. BYRNE, JOHN F. O'ROURKE, PAUL G. BROWN, J. V. DAVIES, JAMES FORGIE, W. C. PARMLEY, T. KENNARD THOMSON, F. LAVIS, CALVIN TOMKINS, AMOS SCHAEFFER, AND E. E. R. TRATMAN.

Mr. Byrne.

EDWARD A. BYRNE,* M. AM. SOC. C. E.—The purpose of this discussion is to call attention to some of the reasons for constructing a vehicular tunnel to connect New York and New Jersey, and to discuss the merits of the various types of tunnels proposed.

Before proceeding, however, it might be well to state that, although the construction of a bridge across the Hudson River had been agitated for many years, it was not until 1906 that any official action was taken by the States of New York and New Jersey. In that year both States appointed Bridge Commissions to report on the advisability of building a bridge across this river. In 1913 additional powers were granted to the New York Commission by the Legislature, which enabled it to direct its attention to tunnel construction, the New Jersey Commission having received like powers from the Legislature of that State.

In February, 1913, Messrs. Jacobs and Davies reported to the Commissions that a tunnel was entirely feasible, and recommended two tubes, to be driven by the shield method—one for east-bound traffic and one for west-bound—each with a roadway to have a width of 17 ft. and head-room of about 12 ft. 6 in., the inner diameter of the tunnels

* New York City.

Mr. Byrne.

to be 22 ft. and the outer diameter 25 ft. This is shown by Fig. 1. The New Jersey terminal was to be on 12th Street, Jersey City, and the New York terminal on Canal Street, as shown by the plan and profile, Fig. 2. For lining, cast-iron was recommended, with a concrete facing. In 1910, this firm had prepared a plan for a two-level tunnel, Fig. 3. The lower level provided a roadway 16 ft. wide, with 9 ft. head-room; the upper roadway was to be 18 ft. 6 in. wide, with head-room of 10 ft. 6 in. at the curb and 12 ft. 3 in. at the center. On this upper level there were two footwalks for pedestrian traffic. It was contemplated that fast-moving automobiles would be placed on the lower level and all other traffic on the upper level.

The study for the arrangement of a roadway tunnel crossing beneath the Hudson River by Messrs. Jacobs and Davies, is based on the assumption that it is not probable that any large amount of pedestrian traffic would be likely to pass through such a tunnel, as the distance from shore to shore is about 1 mile at the region of Cortlandt Street, New York, and about ¾ mile at 59th Street. Hence, as much space as possible has been devoted to vehicular traffic, for which separate accommodation has been provided for "Fast" and "Slow", the fast being confined to the lower, and the slow to the upper, roadway.

Air ducts have been shown, to permit of mechanical ventilation.

Ample head-room is afforded for each type of traffic. For example: the highest slow-moving truck is about 10 ft. 3 in. high, and the head-room provided for vehicles of this class is 12 ft. 3 in.

The height of the highest limousine automobile is 7 ft. 10 in., and the head-room provided for fast vehicles is 9 ft. 0 in.

In July, 1916, the Public Service Corporation of New Jersey selected a Board of Engineers to report on the design and feasibility of a vehicular tunnel under the Hudson River. This Board consisted of W. H. Burr, Ralph Modjeski, and D. B. Moran, Members, Am. Soc. C. E., and, in January, 1917, it reported in favor of the construction of a tunnel by the trench method. The section in the river was to be of reinforced concrete resting on timber piles. It was to be, generally speaking, elliptical in section, the inner major axis being 28 ft. 4 in. and the outer axis 36 ft. 5 in. The over-all distance from top of piles to roof was 28 ft. 10 in. One roadway, 17 ft. wide with head-room of 13 ft., and two footwalks, one 5 ft. 6 in. and one 3 ft. 6 in. wide, were to be provided.

In September, 1917, Gen. George W. Goethals, U. S. A., M. Am. Soc. C. E., was retained by the Joint Commission to report on the best type of tunnel to be built. In November of that year he recommended the construction of a single tunnel with two levels, to be constructed by the shield method, and pre-cast concrete blocks were to be used in place of cast-iron with concrete lining. No change in location was recommended.

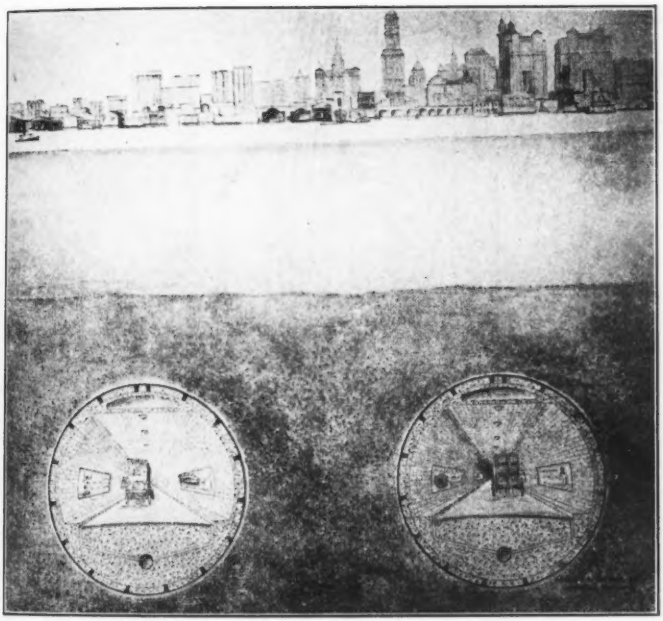

FIG 1.—CROSS-SECTIONS OF ONE-LEVEL, TWO-WAY EACH, VEHICULAR TUNNELS.

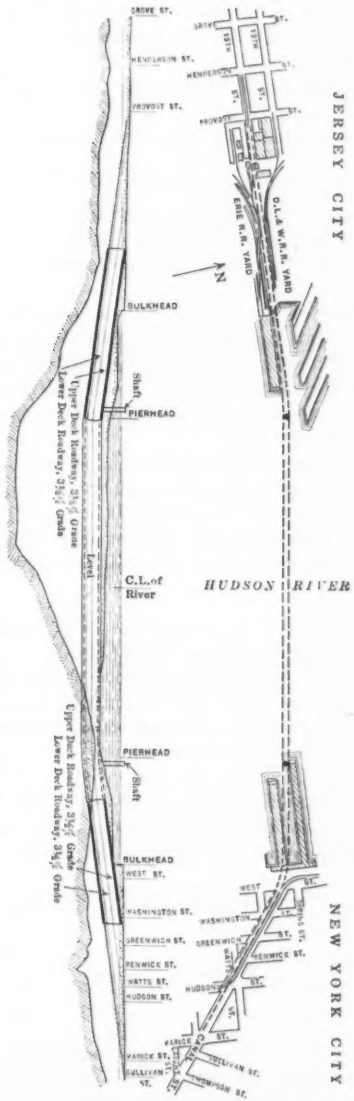
Mr. Byrne.



PLAN AND PROFILE OF PROPOSED NEW YORK AND NEW JERSEY VEHICULAR TUNNEL.

FIG. 2.

Mr. Byrne.

The following are the estimates of cost of the three tunnels:

1913—Jacobs and Davies, for two tubes, "pre-war estimate,"	$11 000 000
1917—Burr, Modjeski, Moran, one tube, "normal prices,"	6 899 000
1917—Gen. Goethals, one tube, "war prices,"	12 000 000

REASONS FOR THE CONSTRUCTION OF A VEHICULAR TUNNEL.

1.—Reduce vehicular congestion at the ferries.

2.—Prevent recurrence of possible coal and food famines, due to interruption of navigation on account of weather or labor troubles.

3.—Free part of river front now occupied by railroad companies for car-float and freight-lighter deliveries, by having freight delivered to New Jersey and hauled by trucks to New York, and *vice versa* for freight from New York. New Jersey has plenty of room for freight terminal expansion, but New York has practically none.

4.—Reduce cost of handling freight at New York by eliminating great trucking waste due to delay in receiving and delivering freight to railroad terminals. It will save the cost of rehandling at New York terminal. The expense of operating through the tunnel will more than offset lighterage and terminal charges in New York.

The construction of the tunnel has been recommended by all the substantial organizations of New York City.

The New York Assembly has passed a bill authorizing the New York Commission to enter into a contract with the State of New Jersey for its construction. This contract, to become effective, must be ratified by the United States Congress.

The Assembly bill carries an appropriation of $1 000 000, and, if it becomes a law, practically binds the State of New York to an expenditure not to exceed $6 000 000 as its share for the tunnel.

New Jersey has enacted legislation to provide a sum equal to that of New York.

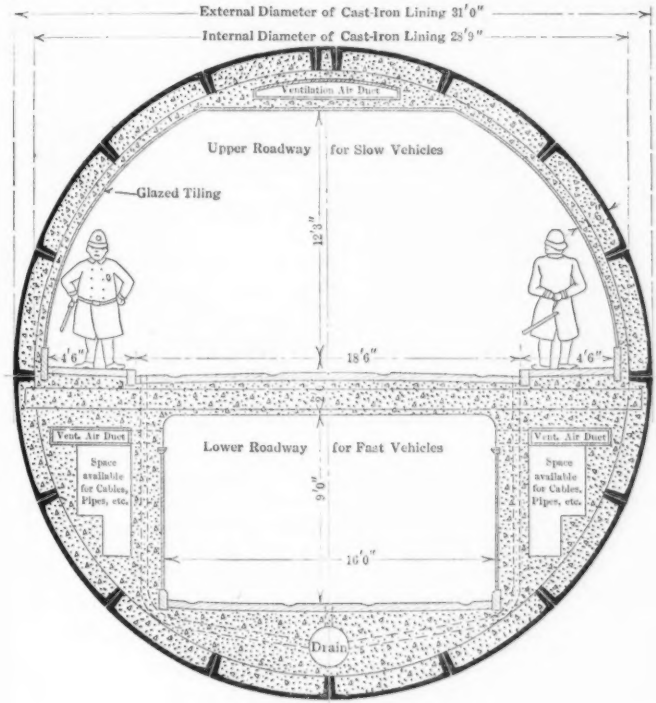
The estimated annual capacities of the three designs under consideration are:

Jacobs and Davies	5 000 000	vehicles.
Burr, Modjeski, Moran	15 417 600	"
Gen. Goethals	36 500 000	"

Messrs. Jacobs and Davies present no details as to what speed and spacing were assumed. Messrs. Burr, Modjeski, and Moran assumed 10 miles per hour and 60 ft. spacing, from center to center of vehicles.

In calculating the capacity of Gen. Goethals' plan, it was estimated that 100 000 vehicles in both directions could pass for 24 hours, as follows: Mr. Byrne.

	Speed, in miles per hour.	Distance, center to center.	Number of vehicles per hour.
Horse-drawn vehicles	3	50 ft.	300
Slow motor vehicles	9	60 "	800
Fast motor vehicles	15	80 "	990
Estimated hourly capacity			2 090
Total estimated capacity, in both directions, for 24 hours			100 320



ROADWAY TUNNEL ACROSS HUDSON RIVER.
STUDY FOR SUGGESTED ARRANGEMENT OF ROADWAYS, ETC. IN TUNNEL 31'0" EXTERNAL DIAMETER.
Nov. 18, 1910

FIG. 3.

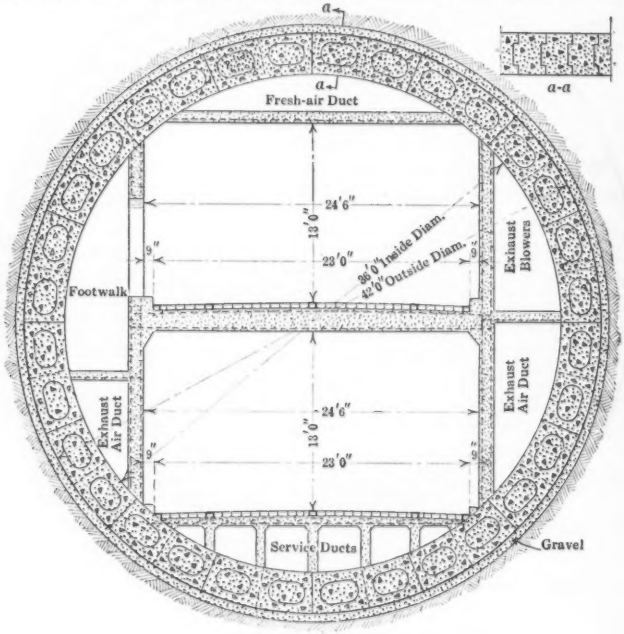
Mr. Byrne.

Applying Gen. Goethals' estimate to the design of Messrs. Burr, Modjeski, and Moran, and bearing in mind that the capacity for a single line of traffic must be controlled by the speed of the slowest moving vehicle, this tunnel would have a capacity of 14 000 vehicles in both directions per day, or 4 646 000 per year.

Applying Gen. Goethals' estimate to the plan of Messrs. Jacobs and Davies, it is estimated that 52 800 vehicles can be passed in both directions in 24 hours, or 19 272 000 annually.

The five ferries, at Cortlandt, Barclay, Chambers, Desbrosses and Christopher Streets, from which this tunnel would tend to take traffic, carry about 10 000 vehicles daily. It is estimated that the tunnel would attract at least 60% of this ferry traffic, or 6 000 vehicles daily.

The Delaware, Lackawanna and Western, Erie, and Pennsylvania Railroads carry across the Hudson daily 1 500 freight cars in each direction, a total of 3 000 cars daily. Assuming that these cars con-



TYPICAL SECTION
NEW YORK AND NEW JERSEY VEHICULAR TUNNEL
CROSS-SECTION OF A TWO-LEVEL, THREE-WAY EACH,
VEHICULAR TUNNEL
FIG. 4.

tain 20 tons each, 60 000 tons are carried daily. If one-half of this tonnage is hauled through this tunnel on trucks, with an average capacity of 4 tons each, it will require 7 500 trucks to do the work. Adding the traffic directed from the ferries, there results a daily total of 13 500 vehicles, or 4 500 000 annually (333⅓ days per year). Mr. Byrne.

Pleasure automobiles, which would be diverted from ferries north of Christopher Street, have not been taken into account in this calculation. Assuming 1 500 per day as a fair average, the daily total would be 15 000 vehicles, or practically the same number as Manhattan Bridge is now carrying.

This estimate is very conservative, and, if the increased traffic on the East River Bridges for the past few years is any criterion, we may confidently look forward to an increase in traffic of 100% in 10 years in this tunnel.

Table 1 is a statement of the vehicular traffic over the four East River Bridges, taken from the records of the Department of Plant and Structures, and is instructive and worthy of much consideration in determining the type of tunnel for the needs of the estimated traffic to be accommodated.

EAST RIVER BRIDGES. GENERAL STATISTICS.

	Opened.	Length.	Roadways.	Width.
Brooklyn Bridge.....	1883	6 016 ft.	2	16 ft. 9 in. each.
Williamsburg Bridge..	1903	7 308 "	2	20 ft. 0 in. "
Manhattan Bridge....	1909	6 855 "	1	35 ft. 0 in.
Queensboro' Bridge...	1909	7 449 "	1	52 ft. 0 in.

In designing any new bridge similar to these structures, no one would think of taking the roadway widths of the Brooklyn or Williamsburg Bridges as adequate for present-day requirements.

The Manhattan Bridge roadway is 35 ft. wide, sufficient to pass two lines of traffic in each direction. In order to care for the morning and evening rush-hour traffic on this bridge, horse-drawn vehicles are prohibited from crossing from Brooklyn in the evening period and from Manhattan in the morning period. During both these periods this traffic is diverted to Brooklyn Bridge, making it possible to accommodate three lines on Manhattan Bridge from Brooklyn in the morning rush and to Brooklyn in the evening rush.

The Police Department, in order to increase the capacity of Fifth Avenue, removed the isles of safety at 42d Street and at several streets north of that intersection. Formerly, only three lines of vehicles could be operated in each direction. By the removal of these obstructions four lines are now accommodated in the direction of the morning and evening rush periods, and two lines in the opposite direction. The Police Department reports that 18 800 vehicles pass 42d Street and Fifth Avenue in 10 hours.

Mr. Byrne.

FOUR EAST RIVER BRIDGES:

1912, Total number of vehicles, 18 304; 1919, 46 305 vehicles. Increase, 150 per cent.

1912, 11 893 were horse-drawn; 1919, 9 750 were horse-drawn. Decrease, 18 per cent.

1912, 6 411 were motor-drawn; 1919, 36 555 were motor-drawn. Increase, 470 per cent.

1912, Manhattan Bridge, total vehicles, 4 823; in 1919, 14 613. Increase, 200 per cent.

Estimated tunnel traffic, first year after opening, 15 000 vehicles daily, with estimated increase of 100% in 10 years.

The four East River bridges have been the means of the discontinuance of seven ferries (Wall Street, Catharine Street, Roosevelt Street, Grand Street, Houston Street, 23d Street to Broadway, Brooklyn, and 92d Street) across the East River. Similar results, no doubt, will be obtained in the case of the ferries across the Hudson River when the vehicular tunnel is in operation.

The distance along the water-front from Pier 1 to 14th Street is 2½ miles, one-half of which is occupied by railroads for ferry and freight terminals. It is confidently estimated that at least ½ mile of this water-front could be released for other purposes if this tunnel were constructed.

The passage in the New York Assembly of the bill providing for the construction of a tunnel or tunnels, and appropriating funds to commence the work, has very forcibly brought the attention of the public to the work, and criticism has been directed against the design approved by Gen. Goethals. First, it was the matter of ventilation, one of the scientific papers claiming that it would be impossible to ventilate it artificially. This paper, during the past month, has reversed its former opinion.

COUNT OVER EAST RIVER BRIDGES.

Mr. Byrne.

The size of the tunnel and the use of pre-cast concrete blocks in place of cast iron, are now being made subjects of controversy.

The Governor's Reconstruction Commission has invited criticism of the Goethals plan, and a Committee of Engineers has recommended that the type of tunnel for this location be decided by a Committee of Subaqueous Experts.

The points raised by the Reconstruction Commission are:

1.—Is the type of tunnel proposed possible of construction?

2.—After it is constructed, is it usable?

3.—Are the estimates of cost anywhere near correct—in other words, will the State find that it has entered upon a programme of much more expense than it has in sight at the present time?

The size of the tunnel is unusual; its diameter is 42 ft. 0 in., and the diameter of the largest tunnel yet built is 30 ft. 0 in. A special type of shield to drive the tunnel has been designed by J. F. O'Rourke, M. Am. Soc. C. E. This shield, which is divided horizontally into four sections, has multiple air chambers in its forward part, each ending 3 ft. in front of the chamber immediately above, thus enabling the excavation to be done in separate vertical faces. Gen. Goethals has approved this shield, and states that it will do the work of excavating the tunnel.

Concrete blocks have never been used as lining in a subaqueous tunnel. They have been used in a land tunnel in Montreal, driven by the shield method, and have been found satisfactory.

It is known that concrete blocks have been used for bulkhead wall construction for many years in New York City, and no fault has been found as to their durability.

The proposed tunnel will be 9 300 ft. long. The roof is 50 ft. below mean low water. This depth has been fixed in a permit issued by the War Department for a tunnel at this location. For 4 000 ft. the tunnel will be practically level. The grade of each of the approaches is

Mr. Byrne.

fixed at 3½ per cent. Practically similar grades exist on the East River Bridges. The lengths of roadway approaches and grades of these bridges are as follows:

Bridge	Approach	Length	Grade
Manhattan	Manhattan	2 900 ft.	3.10 per cent.
Williamsburg	Manhattan	2 500 "	3.00 " "
		1 500 "	3.5 " "
Queensboro'	Queens	3 600 "	3.4 " "
Brooklyn	Manhattan	1 562 "	3.25 " "

Ventilation experts have advised that the tunnel can be artificially ventilated. It has been stated that artificial ventilation is not necessary. This statement is based on the fact that two vehicular tunnels in London under the Thames are being used successfully without artificial ventilation, although at one of them the ventilation plant has been constructed and is ready for use if found necessary.

The London tunnels referred to are known as the Blackwall Tunnel and the Rotherhithe Tunnel. The Blackwall Tunnel, Fig. 5, is 6¼ miles below London Bridge. It is 6 200 ft. long and is lined with cast iron. The outer diameter of the tube is 27 ft. One roadway, 16 ft. wide, and two sidewalks, each 3 ft. 1½ in. wide, are provided. The minimum headroom is 15 ft. 6 in. The maximum grade is 1 in 36 (2.78%). The tunnel was opened to traffic in 1897. The contract price was £870 000; the cost of property, sites for rehousing, and miscellaneous, amounted to £536 000, a total cost of £1 406 000. The 1917 Report of the Public Service Corporation of New Jersey states that the annual traffic for 1913 was 772 940 vehicles and 3 742 241 passengers. An actual count during a period of 13 hours, in January, 1916, showed that 2 000 vehicles and 7 473 passengers used this tunnel, the greatest number of vehicles for any hour being 219.

The Rotherhithe Tunnel, Fig. 6, is 2¼ miles below London Bridge. It is generally similar in design to the Blackwall Tunnel, with the exception that the outer diameter is 30 ft., making it the largest subaqueous tunnel ever built. It is 6 826 ft. long, and has a roadway 16 ft. wide and two footwalks, each 4 ft. 8½ in. wide. The maximum grade is 1 in 37 (2.7%). The length of the river portion, between shafts, is 1 535 ft. The tunnel was opened to traffic in 1908. The contract price was £1 088 484; the cost of property, sites for rehousing, and miscellaneous, amounted to £911 516, a total cost of £2 000 000.

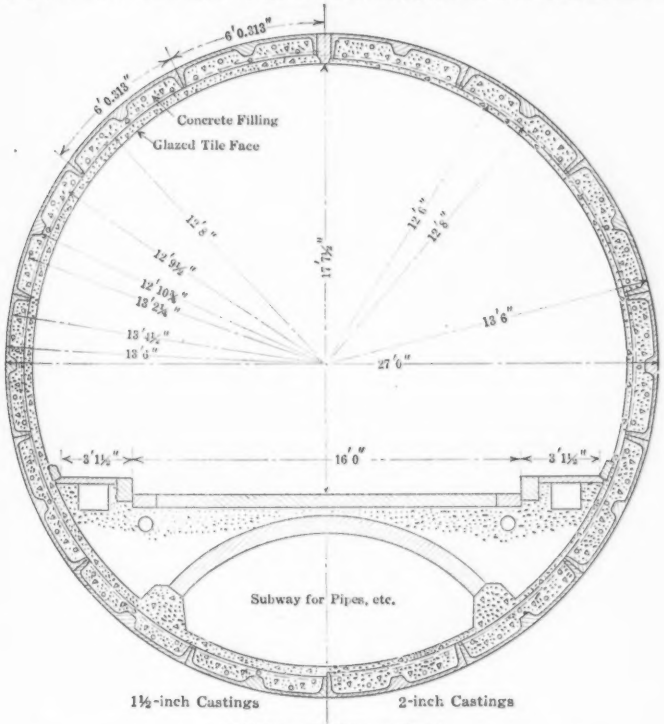
The 1917 Report of the Public Service Commission of New Jersey states that the annual traffic for this tunnel for 1913 was 937 946 vehicles and 3 360 067 passengers. From a count made in 1914, for a period of 12 hours, 8.00 A. M. to 8.00 P. M., 2 040 vehicles used this tunnel.

The heaviest traffic for any one hour, from the foregoing records of these two tunnels, was 219 vehicles for the Blackwall Tunnel.

The speaker's estimate of traffic through the proposed tunnel, of 15 000 vehicles per day, would mean a maximum of 1 300 vehicles per hour of heaviest traffic. This estimate is made from the count taken at the Manhattan Bridge on March 14th, 1919, on which day there was a total of 14 613 vehicles recorded as using the bridge for 24 hours, the heaviest hour traffic being 1 166 vehicles. Mr. Byrne.

At a hearing before the Reconstruction Commission, Mr. O'Rourke submitted a proposal to build the tunnel complete ready for use for the sum of $11 500 000.

In answer to the criticism raised at the hearing, that the patented shield, concrete blocks, and gravel backing gave him exclusiveness in



BLACKWALL TUNNEL, LONDON

Mr. Byrne.

bidding for the contract, he proposed to refer his interest in the matter to the Chamber of Commerce, with full power to fix his compensation for giving license to any contractor to use all the patents for the driving of this tunnel. This compensation was not expected to exceed one-quarter of the saving made by their use.

From an experience of many years with traffic on long-span bridges, there is no doubt in the speaker's mind that narrow roadways are not to be recommended for present-day traffic, as they are sources of congestion and blockade, particularly during the heaviest traffic periods. The failure of one vehicle to maintain its position at these times has been frequently the cause of the entire interruption of the vehicular

FIG. 6.

FIG. 7.—SHOWING HOW AN ADDITIONAL 3 FEET, TO A 20-FOOT ROADWAY, WOULD PERMIT OF THREE-WAY TRAVEL.

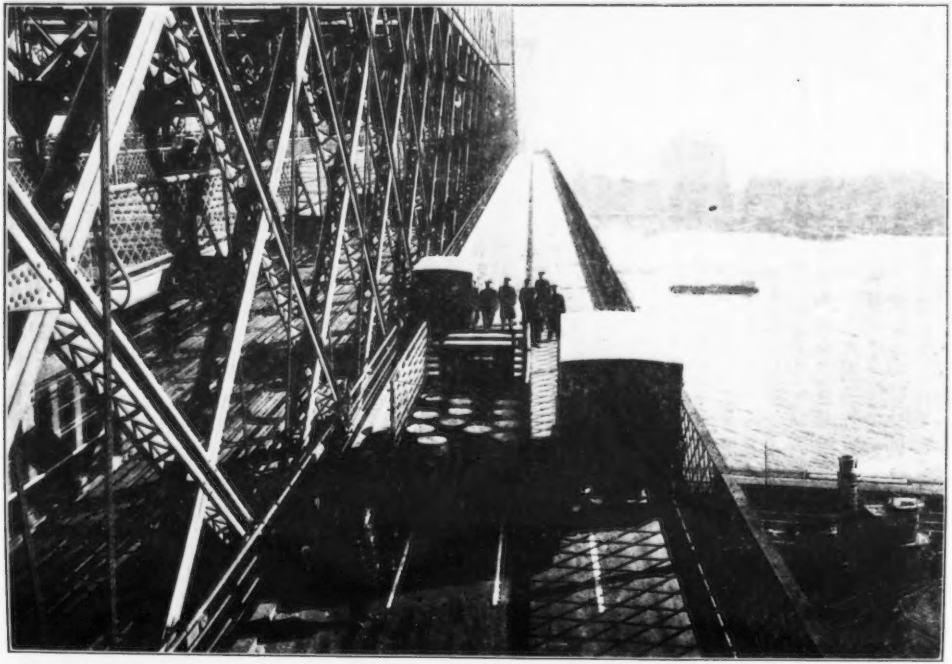

FIG. 7.—SHOWING HOW AN ADDITIONAL 3 FEET, TO A 20-FOOT ROADWAY, WOULD PERMIT OF THREE-WAY TRAVEL.

traffic across bridges which have narrow roadways. The Brooklyn and Williamsburg Bridges are examples of this narrow roadway error, but the roadways of the Manhattan and Queensboro' Bridges are free from congestion from this cause. Fig. 7 shows that the addition of 3 ft. to a 20-ft. roadway would permit of 3-way travel. Mr. Byrne.

It would require four 2-line vehicle roadway tunnels to equal the capacity of the tunnel approved by Gen. Goethals. The cost of these would be $22 000 000, by pre-war estimates, as compared with $12 000 000, by present-day prices, for the Goethals design.

Therefore, from a cost and efficiency point of view, the problem seems to be easy of solution.

JOHN F. O'ROURKE,* M. AM. SOC. C. E.—Mr. Byrne's description of the general conditions of the tunnel traffic question—about which he is probably as well informed as anybody in the world—and also what he has shown of the different types of tunnels, including that in which the speaker is interested, will probably leave little to be said on the subject of highway traffic, and so this discussion will be confined to certain novel features of the proposed Hudson River Vehicular Tunnel and some of the new methods involved. Mr. O'Rourke.

It is properly said that that tunnel is a large one, and that there has been no other like it in some of its features, but, in general, it is similar to the other Hudson River Tunnels, and in its vital features is exactly the same. The shield, also, is like other shields in all essentials, and, in addition, possesses two simple improvements which would have been used on former shields if they had been known.

Certain patents have been issued to various parties for methods of dividing the face of the shield into different levels, so as to avoid the unbalanced pressure caused by a height equal to the whole diameter, which exists where there is one chamber from top to bottom at the front of the shield. The first of these patents, for subdividing the front of the shield, was issued to Brunel in 1818, but it had nothing to do with compressed air, because that was before its use had been introduced in tunneling. The first patents for multiple air-pressure shields were issued about 1888. In 1891 the Pearsons, of S. Pearson and Son, of London, were granted a patent on a multiple air-pressure shield, the drawings of which show four levels, the same as the shield now under discussion.

At about the same time, the closing of the opening between the tunnel lining and the tail of the shield, in order to prevent the escape of air or the inflow of water, was attempted by Sir E. W. Moir, M. Am. Soc. C. E., of that company. He obtained two patents on the subject. D. L. Hough, M. Am. Soc. C. E., also obtained patents on means to close that opening.

* New York City.

Mr. O'Rourke.

The speaker has no knowledge that any of the tail-closing devices were ever tried, but the multiple air chambers were, and were not a success, because the faces of the excavation were all in one vertical plane. When the excavation had been carried sufficiently far downward, the air crept around the face of the floors from one level to another until the same pressure existed from bottom to top in all the chambers. In the new shield, as each chamber is projected beyond the one above, this cannot happen, because the air passes into the ground, where it expands as it rises, passing each chamber at less than the pressure in that chamber.

If there is anything that the speaker's experience with compressed air has taught him, it is that as soon as air escapes into the ground it expands and rises, for, no matter what its pressure was when it got out, it instantly takes the pressure of the ground-water it is in. The several chambers have the same air pressure as the ground-water at the level of their floor, and thus have a higher pressure than that in the ground in front of them, and, consequently, the escaping air cannot hold enough pressure to enter any chamber it is passing. If, for any reason, it moved backward as well as upward, across the step between the vertical planes of the excavation, the ground friction would cause an additional reduction in its pressure, further preventing it from entering the chamber above. Therefore, nothing is clearer than the fact that air escaping into the ground from one chamber cannot enter another chamber in which the air pressure is greater than that of the ground-water in front of it.

It has been stated that perhaps a boulder might be met at the front of a floor when shoving the shield, a contingency which is most likely. In pulling in or blasting that boulder, a hole is made of the same size as the boulder. The experts say: "What is to prevent air in large volume from going through this hole and entering the chamber behind?" The answer is that a large volume of air could not be contained in a hole the size of a boulder, and that the boulder must have been at least the width of the step in front of the chamber. All these things relate only to the work on shore, where sand and gravel are found. Under the Hudson River there is only silt, and the upper levels of the shield would never be opened to take in any of that. The effective cover could be counted on as from the top of the opening through which silt is being admitted into the shield, to the bed of the river or the top of the clay blanket, as the case may be.

As already stated, the efforts heretofore made to close the opening, between the tail of the shield and the tunnel lining within it, reached the point of taking out patents for devices. Stuffing the opening at the top with cement bags, or blocking it with steel plates against the end of the last ring, are about all that has been done to impede the escaping air. The bags were blown out at the next shove, and the

steel plates had to come down in order to erect the next ring, so that no real continuous checking of escaping air was accomplished. As the back of the shield under the lining was inaccessible, nothing was ever done to stop the water from entering at the bottom, except to raise the air pressure while the bottom plates were being set, whenever the water gave trouble. In order that the multiple air-pressure chambers at the front of the shield might have practical value, it was essential that this opening should be closed continuously against the escape of air or the inflow of water. Mr. O'Rourke.

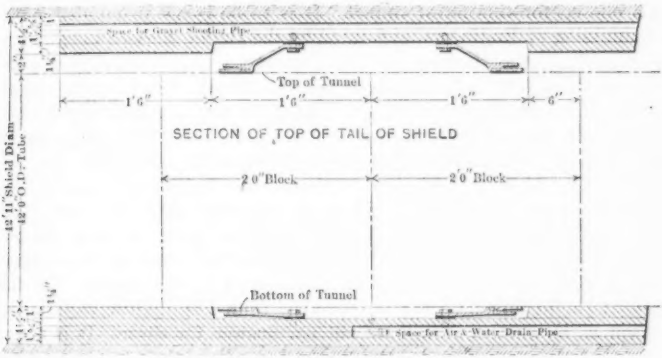

FIG. 8.

Fig. 8 shows how this is to be done by the simple expedient of providing a recess in the tail of the shield by two 1¼-in. steel-plate rings having a space between them in which two flap-valves, extending around the whole circumference, are fastened to the tail. The back one faces backward, and the water seeking to enter presses it down on the lining, making a water-tight seal, like the foot-valve of a pump. The front one faces forward, and the air pressure forces the flap down on the lining, making an air-tight seal, like a valve in an air compressor.

In this way the water is excluded and the air is contained, irrespective of the water or air pressure, so that, in connection with the multiple air-chambers, the excavation may be done without much unbalanced pressure under greatly reduced cover, and the tunnel itself can be given such pressure as may be most desirable, independent of the immersion.

It is likely that some lubricant may be used on the lining, to facilitate the slipping of the flap-valves during the shoves, and provision will also be made to pump back into the tunnel any water or

Mr. O'Rourke.

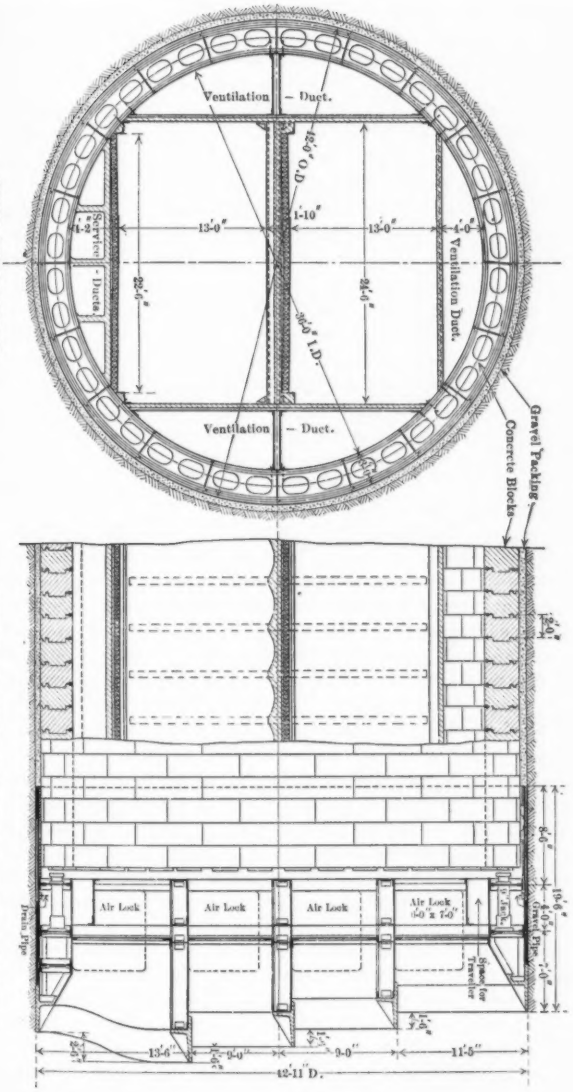
air that may accumulate between the valves and interfere with their operation. The valves will be strongly constructed, and should last through the distance the shield has to go, but, if necessary, they can be readily repaired or replaced.

Another matter which should be mentioned is the information obtainable in regard to the Canal-12th Street Line. It is obvious that that location must be right, because everybody who has projected a down-town tunnel has selected it. It was chosen first by Messrs. Jacobs and Davies. It was afterward adopted by the Commission of Engineers for the Public Service Corporation of New Jersey, and was also chosen for this latest tunnel. It is to be borne in mind that the Commission of Engineers, appointed by the Public Service Corporation to investigate the Hudson Vehicular Tunnel question, was given *carte blanche* as to the information it was to obtain, and also the extent to which its expenses might go. The three men on this Commission are among the most prominent bridge and foundation engineers in the country, and have had great experience in obtaining data for plans. The work of exploration required for foundations for bridges or buildings is necessarily much more extensive than any exploration for a shield-driven tunnel. In one case the work is from the top down, and it is important to know the material in which the excavation will be made and the kind of material at the bottom. In the case of shield tunnels, what is above the tunnel is of little importance, except as to whether it will or will not answer for cover. It is necessary that the ground under the tunnel be sufficiently compact to carry the load, and this can be done, even by silt, as experience shows, probably because the structure weighs less than the ground it displaces. As the shield can be driven through any kind of material, a few good borings answer all practical requirements, particularly in the Hudson River, where the shores and river bed have been tunneled so often. The same parties who were employed on the speaker's Pennsylvania Tunnels were engaged by the Commission, and made thirty-eight core borings into the rock from end to end of the tunnel site, even where the rock was 200 ft. below the grade. Therefore, the rock profile is very well known.

In addition to these borings, forty-two test piles were driven in the river bed. As the bed of the river consists of silt above the rock, with a foot or two of gravel and sand lying on the rock, the Commission is justified in the statement made in its report that it obtained the first and only complete rock profile under any of the rivers about New York City.

Fig. 9 shows the proposed interlocking concrete block tunnel, and the details of the blocks are given on Fig. 10. The projections are ¾ in. longer than the depth of the recesses, so that the blocks do not come in contact, except at the bottom of the recesses; that is to say,

Mr. O'Rourke.



CROSS-SECTION OF TUBE.

LONGITUDINAL SECTION AND VIEW OF TUBE; SECTION OF SHIELD

FIG. 9.

Mr. O'Rourke.

the pressure caused by shoving the shield is transmitted through the lines of projections and recesses, so that spawling is avoided, and the other parts of the joints are free and accessible for water-proofing, caulking, and grouting.

A key-way is moulded at the top of the joints, on one side and one end of each block, in which is put a mastic gasket, opposing which are projections from the opposite side and end, which compresses the mastic, thus completely filling all joints at the top.

At the bottom of the joints a caulking seam will be moulded, and filled with a well driven caulking of oakum and tar, as a final line of defense against the entrance of any water that might pass the mastic and grout portions of the joints. Three blocks will be cast at a time, so that where the key-block shows at the top, requiring three special blocks, those three would be made in one operation. The parts of the joints inside the key-way and caulking seam, except a narrow smooth band for an exact ¾-in. joint in which spacers will be placed while the blocks are being erected, will be left purposely rough.

The size of the block, measured from the bottom of the recess to the face of the projection, must be uniform throughout, and all the moulds will have machined faces at these points, maintained at exact distances apart. There ought to be no more difference in the blocks, as to projections and recesses, than in fine machine work, because concrete fits its mould, and the moulds would be made with extra care at those points. Therefore, the blocks can be relied on to maintain contact throughout the line of projections and recesses. The jacks never let go of the blocks, except that when an adjoining block is being set, one jack is released on each side of a joint, after which the pressure is immediately restored. This means that the concrete block rings are always under compression. Assuming one-fourth of the jack power to be used for compression between shoves, this would equal about 50 lb. per sq. in. of ring. Concrete weighs 1 lb. per sq. in. for each foot of height, so that the rings are always under a compression equal to the weight of a section of tunnel, 50 ft. long, turned up on end; thus the rings are like courses in a pier, 50 ft. below its top, which are held in place by that much superimposed weight. Therefore the concrete throughout the tunnel is given an initial compression which renders tension members unnecessary, as no longitudinal tension can exist.

It is proposed to use gravel packing around the tunnel lining throughout. This gravel is blown simultaneously through a number of rubber hose pipes inserted in passages in the tail of the shield. The gravel will be blown from many tanks into the space made by the shield outside the lining as it moves forward, completely filling that space. The gravel is to be composed of an equal mixture of coarse and fine grits, which are about the size of buckshot and birdshot.

Mr. O'Rourke.

The effect of the impact of the gravel on itself is to crush it into a hard mass, cemented like embryo sandstone by the powder into which some of it is reduced. In building inter-track stations, there has been occasion to take out portions of tunnel lining, where gravel packing had been used, and the lining seemed to be encased in sandstone. The Public Service Commission engineers took photographs showing cracks in the ground into which the crushed gravel ran, the same as grout would, and it was equally hard, for all practical purposes. In connection with the Hudson River silt, it is certain that gravel packing will hold the ground undisturbed and solidified where it surrounds the tunnel, so that its bearing power will be greatly improved.

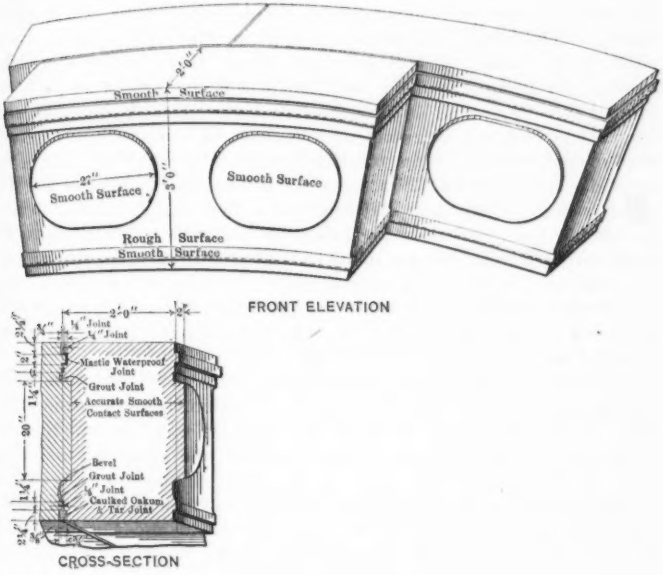


FIG. 10.

Some question has been raised as to the use of gravel packing in silt, through which the propelling air could not escape. In places where the ground is impervious, the shield provides means for returning the air that carries the gravel back into the tunnel through the same passageway that contains the hose. In a tunnel in Detroit, where bad settlements were occurring, gravel packing is now being used successfully in clay.

Mr. O'Rourke.

The experience during the construction of the Pennsylvania Tunnels was that there were serious irregularities of pressure in the silt against the sides of the lining for about a year after the tunnels were driven. Shores and tie-rods were used throughout to maintain the rings in circular form, and these had to be retained for more than a year, after which the ground had settled uniformly around the tunnels, and the cast-iron rings retained their form unaided while the concrete lining was being placed. This would indicate that, if gravel packing had been used to prevent the disturbance of the silt, there would have been no trouble from unequal pressures at any time. It also proves that the alleged differences of pressure in undisturbed ground around the circumference have no distorting effects. A test was made in the Willoughby Street Tunnel by slacking off the turnbuckles. This was done without causing the slightest spreading of the sides of the tunnel, so that it is safe to say that the gravel packing enables the ground to hold the tunnel and the tunnel to hold the ground, in silt as well as in any other material; and that this large tunnel can be built, if gravel packing is used, without any deformation of the concrete rings or disturbance of the equilibrium of the ground. Moreover, the 36-in. interlocked concrete block rings are very much stronger than any cast-iron rings that could be built within reasonable limits of cost, and there is no question that where the weaker ring held its form assisted only by gravel packing, the stronger one will also, with the same assistance. Besides, these strong rings get further strengthening from the steel columns and floor, securely anchored to the lining so as to take tension or compression at six different parts of the circumference.

The lowest point in the Pennsylvania Railroad Tunnels was 97 ft., and the air pressure was about 25 lb. per sq. in. from one side of the river to the other, that is, much less pressure was required than the immersion would indicate. That answers the question, asked by Paul G. Brown, M. Am. Soc. C. E., as to the men in the bottom chamber working for short shifts while the men in the other chambers would be idle. As a matter of fact, this shield and this method do not call for any greater immersion than the Pennsylvania Railroad Tunnels.

The rock at the New York end of the tunnel would be taken out in a shaft, and not under compressed air.

In reference to the ventilation of the tunnel, an article * appeared a short time ago which was not meant to apply to this tunnel, as it had not been proposed when the article was written. In attempting to describe it, the writer of that article alluded to Mr. Davies' tunnel and to the tunnel of the Public Service Corporation. He assumed 52 sq. ft. as the area through which were to be diluted the fumes of

* *Scientific American.*

about 150 automobiles, averaging 15 h. p. each, and all supposed to be consuming gasoline at the highest rate. He then calculated the velocity and power required by using Kent's formula for ventilating mines. He assumed that the rough surface of the mine passages and the smooth surface of a ventilating duct have the same modulus of friction. As it is 0.002 in one case and 0.007 in the other, it will be seen that there is some difference. That article, however, is used to-day against this tunnel which has 250 sq. ft. of duct area, not to mention more than 600 sq. ft. of roadway which will also be used. Mr. O'Rourke.

The well-known law in regard to the movement of air is that the power required to move it varies with the cube of the volume, or inversely as the cube of the area of cross-section of the tube. If there were 52 sq. ft., 48 000 h. p. would be required, costing $2 600 000 a year. A duct having 104 sq. ft. would require one-eighth as much, or 6 000 h. p. Doubling that area again would give one-eighth of one-eighth of 48 000, or about 800 h. p. The actual duct area of this new tunnel would require about 500 h. p.

Ventilating apparatus was provided for the Blackwall Tunnel, but was never used, and no provision for ventilation was made in the next Thames tunnel. There are half a dozen other vehicular tunnels, none of which has induced ventilation, and where even pedestrians go without danger or inconvenience.

Mr. Parmley has discussed the subject of jacks and the slope that the earth takes around a tunnel, and how much more jack power will be needed. The speaker is familiar with nearly every tunnel that has been built in the vicinity of New York City, and has had to do with a great many kinds, both as engineer and contractor. There is one rule in regard to jacks and resistance to jacks in shields that is as true as that in regard to the weights put on a caisson in order to sink it, and that is, it is a matter of the area of rubbed surface. The diameter or dimensions do not matter. It is the rubbed surface that counts.

There is a rule, and it is more for construction reasons than anything else, that jacks in a shield are placed about 3 ft. apart, so that, if the diameter of the tunnel is known, the number of jacks required will be the same as the diameter, in feet. If a tunnel is to be driven under Brooklyn Heights, where there is 120 ft. of cover, and where the weight on top is several times as great as that on top of this tunnel through the Hudson silt, that rule could be followed as successfully as the speaker has followed it, and no calculations will satisfy him that the jacks he used did not push those shields, because they did.

Then, again, the question of the design of the blocks and the load that is forced on the blocks by jacks, was fully settled at Montreal, where there is a cover of more than 60 ft. above the tunnel, at least 40 ft. of which is that jelly-like substance known as "bull's liver".

Mr. O'Rourke.

The jacks used in the shields there were loaned by the O'Rourke Company to the contractors, Mackenzie, Mann and Company. S. P. Brown, M. Am. Soc. C. E., the Chief Engineer of the tunnel adopted these blocks without any precedent to guide him, and he and his principals are greatly pleased with the results. The speaker was familiar with the work while it was going on, and knows whereof he speaks.

At a recent hearing, in regard to the Hudson River Tunnel, before the Reconstruction Commission of the State of New York, Mr. Brown declared that, although the weight was so great that it crushed the footings of the shield, consisting of three 12-in. I-beams bolted together, with concrete in between, bent the center columns, and sometimes sheared the rivets of the channel-beams at the top of the columns, in no case was a concrete block even deformed. Further than that, with all this weight above, the jacks, approximately 3 ft. apart, pushed the shield, exerting 150 tons when the water pressure was 5 000 lb., and there was not a single case in which a projection on a concrete block was crushed. In other words, this tunnel with interlocking concrete blocks was driven most successfully under difficulties fourfold as great as those that will be encountered by the tunnel in the Hudson River silt.

The use of concrete blocks saves both time and money; nevertheless, the speaker's company is prepared to use either cast-iron or concrete lining.

Mr. Brown.

PAUL G. BROWN,* M. AM. SOC. C. E.—Only two weeks ago the Governor of New York State requested Engineering Council to appoint a committee of five engineers to advise the Reconstruction Commission of the State of New York in regard to proposed public works projects. To act on that committee two engineers of this Society were chosen. One of the first things the Governor asked the Reconstruction Commission to do was to report on the vehicular tunnel under the North River. It happened that only one member of the Engineering Committee had had tunnel experience, and as the Committee believed that it ought not to pass on such an important work, involving so many technical details, it recommended that the Governor refer the matter to a paid commission of properly qualified engineers.

Some months ago this Society, thinking that it was not performing its full functions in the affairs of the State and the Nation, appointed a Development Committee. This Committee has not yet reported, but, as it has seemed to be the desire that this Society should fill a large place in the community, the members now have a chance to assist the Governor of the State and perform that larger function, for, if those who are familiar with this kind of a proposition will say what they think about it, they will do a very good work for the State, and will

* New York City.

help the Governor, as he is very anxious to get all kinds of public improvements going. Mr. Brown.

There are many members of this Society who are capable of discussing such a project. Mr. M. L. Quinn has had much experience in tunnel construction, as well as Messrs. Davies, Forgie, Lavis, Mason, Haggard, Snyder, and Shailer; and there may be many others. If they will say what they think about this tunnel, the Committee and the Society can get behind their opinions without any question.

The Committee has been asked a number of questions, a few which are as follows:

Can such a tunnel be ventilated?

Can a shield, 43 ft. in diameter, be constructed of sufficient strength, without prohibitive weight and expense?

Would pre-moulded concrete blocks have sufficient strength to withstand the thrust of such a shield?

Could pre-moulded concrete blocks of the design suggested be made water-tight?

Would such blocks have sufficient strength to support the tunnel structure?

Is it possible to maintain compressed air at several stages of pressure in the face of a shield?

With four sets of air locks in the shield, would the concentration of so much effort at this point prove a serious obstacle?

Can a shield of such size and strength be kept to line and grade?

It is a well-known fact that a shield, if it cannot move ahead, will move downward; and, with the lower part of such a shield projecting so far beyond the upper, if it did settle, could it ever be brought up to grade?

This shield is 93 ft. below mean low tide, or 20 ft. lower than would be necessary with a smaller tunnel with correspondingly lower pressure. In the bottom chamber, through the rock sections, the "sand hogs" would only work short hours. The shield could move no faster than the bottom chamber. Would this make the progress so slow that the cost would be prohibitive?

Can any system of concrete blocks be designed for this tunnel that would be a proper substitute for the usual cast-iron lining?

Would the congestion of traffic at the terminals, due to the concentration into one tube, prohibit that type of construction?

Would two single tubes, if carrying two lines of traffic in each direction, be sufficient for the present traffic needs?

What units of cost are used in making the estimate of $11 500 000 for this tunnel?

The speaker hopes that this discussion will bring out many facts concerning this project.

Mr. Davies.

J. V. DAVIES,* M. AM. SOC. C. E.—The speaker is deeply interested in Mr. Byrne's presentation of this proposition, particularly with reference to the traffic. Information in respect to the actual volume of traffic to be expected in connection with these proposed highway tunnels has always been more or less deficient, and Mr. Byrne's statement of that feature is decidedly illuminating.

The speaker admires Mr. O'Rourke's presentation, and the ingenuity with which he solves all the various problems in connection with his tunnel. As Mr. Byrne, in his opening discussion, has mentioned the speaker's name, it would be well to clear up a little history in that regard.

A week ago, the speaker attended a meeting of the Reconstruction Committee, and stated then that he had been connected with the Interstate Commissions more or less, for some years. About 1910 the speaker's firm made a study of this proposition, and, as tunnel engineers, came into connection with the New Jersey Commission, in the first instance, and, later, with the New York Commission, in working out this vehicular transportation proposition.

In 1913 his firm reported to the Commission on this subject, and advised that two plans were feasible; one was a tunnel of large size, approximately 30 ft. in diameter, which could be built in pairs, one for east-bound and one for west-bound traffic. Each of these could be further divided, for slow vehicles on one level and for fast vehicles on a second level, and thereby give great capacity for traffic.

The other proposition was for smaller tunnels, of the general size of those built by the Pennsylvania Railroad; and, at the request of the Commissions, that one single and definite plan should be reported on to the Legislatures, his firm prepared the report of the Commissions, which was forwarded in 1913 to the Legislatures of the States of New York and New Jersey, recommending a pair of tunnels of the smaller size.

Now, the point of this was very simple. The members of the speaker's firm had no information, other than their own personal knowledge, of the conditions north and south of the location that had been laid out for this vehicular tunnel, and were not prepared to make any wild gamble as to what might be done, but preferred to stand by what they knew could be done; and, further, the two Commissions had no money available with which to make investigations of any sort.

In 1914, George D. Snyder, M. Am. Soc. C. E., presented this subject of subaqueous vehicular tunnels, in a paper† which contains most of the structural information presented by Mr. Byrne. That paper treats of all subaqueous vehicular tunnels, and covers Mr. O'Rourke's proposition, as well as the various plans of open-trench tunnels.

---

* New York City.

† *Transactions*, Am. Soc. C. E., Vol. LXXVIII (1915), p. 252.

Mr. Davies.

Now, there is one thought that should be brought out clearly, and that is, that there never has been at any time any assembling of these various propositions, so as to compare them on the same basis of costs. Mr. O'Rourke's plan for a very large tunnel may be quite feasible, but it would have to be considered in detail before the speaker would feel equal or capable of saying whether or not it was desirable. These plans must be brought to a sane basis for comparison.

Mr. Byrne states that the tunnels, to give a capacity equal to Mr. O'Rourke's design, would require four of the type which the speaker had recommended to the Commission, and would cost $24 000 000, whereas Mr. O'Rourke's design would cost $11 500 000. There is evidently something radically wrong in such a comparison. This thought should be brought up squarely. The displacement and consequent excavation of a 43-ft. tunnel, which represents the shield that Mr. O'Rourke has designed, represents 53 cu. yd. per running foot. A pair of 24-ft. tunnels represents only 33 cu. yd. per running foot. There is 60% more excavation per running foot in the large tunnel than in the two of smaller size.

Of the cost of construction of a tunnel, more than 50% is represented by the labor and other costs expended in producing the hole, that is to say, the excavation and contingent work to prepare for the insertion of the lining; and probably not more than 20% of the total cost is in the iron lining itself. This fact is worthy of careful consideration.

Then, another point: The builder of this large tunnel must consider that the roof grade is approximately at the same roof grade as the smaller tunnels, that is, any excess in diameter is at the bottom. The intersection with the rock reefs on each side comes at earlier points at the two ends, and the most expensive part of the tunnel driving is from the moment the rock reefs are touched and work has to be done in a rock bottom with a soft ground top; thus, the increase in the cost of the excavation comes sooner and is in larger amount.

There are approximately only 3 000 ft. between the rock reefs on each side. On the New Jersey side, above the rocks there is sand, which is as bad as rock, inasmuch as every bit of it has to be excavated. The shield cannot be shoved into it an inch until it has been excavated. That proposition has to be considered.

Another point, with respect to New Jersey, is the fact that any new tunnel must be located so that it will be above the plane of the tunnels of the Hudson and Manhattan Railway, the tubes of which at the location of intersection, are superimposed, lying one on top of the other, leaving a comparatively shallow depth between the surface of the yards of the Erie and Lackawanna Railroads and the roof of the tunnels below, so that whatever construction, of whatever type, must go above those tunnels at that point of intersection.

Mr. Davies. Therefore, although this discussion should, and undoubtedly will, draw out a lot of very valuable information, it is not thought that any one will arrive at a very definite conclusion; and, further, all these plans should receive very serious and careful consideration on their merits, at some time or other, before any definite, final adoption of any one of them is made.

Mr. Forgie. JAMES FORGIE,* M. AM. SOC. C. E.—The speaker is surprised to find that this public highway tunnel discussion pertains chiefly to a shield-driven tunnel of definite design, having an external diameter of 42 ft., and to be lined with pre-cast concrete blocks.

The economic necessity of a highway tunnel under the Hudson is quite obvious, and is only second to the pressing necessity for a railroad freight tunnel connection, though it is of little consequence which is built first. In 1892-96, in London, they built a vehicular tunnel, in which the speaker obtained his baptism of compressed air, the Blackwall Tunnel. This tunnel was so successful that another was built, the Rotherhithe Tunnel, completed in 1908. London's industrialism can distribute itself in almost any direction, and is not confined, as is that of Manhattan; so that, for New York City there must be still greater reason for a vehicular tunnel to connect it with the mainland. New York City is a clearing house for the continent, and in that capacity has a very great, pressing, and all-sufficient duty to discharge.

The speaker feels considerable diffidence in saying anything on the matter of design and method of construction of this tunnel; but is attracted by Mr. O'Rourke's proposed cross-section which is to accommodate two superposed roadways, each with three lines of traffic in one direction. Of course, a one-way road of three lines of traffic has advantages over one with two lines of traffic, but, to realize it in one tunnel, in the way suggested, may or may not be economical.

There are many things that require serious study and consideration in connection with the construction of a tunnel of normal size, and each tunnel project, even under the same waterway, becomes an individual problem. Much as the speaker would like to give his unqualified opinion, he does not think it wise to do so, on this occasion, on this large tunnel, of 42 ft. external diameter, lined with concrete blocks, and proposed to be constructed with a multi-air-pressure shield. Therefore, he wishes it to be understood that anything he may say should be considered as general, but definite enough to give cause for reflection. He hopes he does not seem to be obstructive or over critical, but, from practical experience, he has reason to believe that a shield 42 ft. in diameter in this case presents unusual difficulties. With probably unusual knowledge as to the conditions of tunneling under the North River, conditions which thus far stand

* New York City.

alone, the speaker feels he is on well-known ground in dealing with tunnel problems under that waterway. Of the matters requiring notice he will mention only a few, and will refrain from detailed comment on the proposed shield and methods, beyond saying that he believes that Nature, as represented in atmosphere and geology, would not adjust itself to either in a way to conform with the practical requirements of tunneling. A shield and its tunnel lining constantly and harshly disagree; each must have a simple and tough constitution, free from pulmonary troubles suggested to the speaker by the proposed shield and conjunctive mining methods. Mr. Forgie.

On the New York side, at the Canal Street location, any tunnel, large or small, would be interfered with by a stretch of rock reef, and, the larger the tunnel, the greater would be the length of this interference, or tunneling in part rock overlaid with silt. The harbor dredging plane is 40 ft. below mean low water, and the minimum cover, in the speaker's opinion, should be about 20 ft.

With a tunnel 42 ft. in diameter, the length of this mixed ground to be tunneled through would be much greater than with a smaller or single-deck tunnel, and a greater differential air pressure would be required during the excavation of the rock reef. Any differential air pressure required would be 9 lb. greater than in a tunnel of the size of the Pennsylvania Railroad Tunnels, and those who are experienced know the difficulty of providing extra cover to meet such a condition and the trouble of keeping it in place.

The speaker is bearing in mind that this is solely a North River tunnel discussion, and that, while shoving a shield blindly through the silt, the air pressure used is generally the equivalent of a hydraulic head of from 5 to 10 ft. above the crown of the tunnel; but, also, when it is necessary to excavate in this selfsame silt ahead of the shield, the air pressure had to be about equal to the hydraulic head. The latter would be the air condition when excavating the rock reef, so that, if the air pressure required to dry out the ground over the rock surface near the invert of a 23-ft. tunnel was 6 lb. greater than is necessary at the crown, then, under similar conditions, this differential force would be 15 lb. in the large tunnel in question. This, added to the air pressure necessary at the crown, requires a somewhat impossible blanket cover.

This large tunnel would require a shield with a cross-sectional area of more than three times that of the Pennsylvania Tunnels and about seven times that of the Hudson and Manhattan Railroad Tunnels. In passing through silt, the latter were driven by displacing almost all the silt, and taking in little or none of it. This plan was tried on the Pennsylvania Railroad Tunnels in silt, but the grade could not be maintained, the tunnel rising unduly above it. Therefore, an average of about 35% of the tunnel displacement had to be

Mr. Forgie.

taken into the tunnel, at times none, at other times from 10 to 100%, but on the average, about 35% of the tunnel bulk throughout the entire length in silt. To the speaker these two cases indicate that the larger tunnel will require a greater proportion of silt to be taken in, and also creates questions in one's mind, concerning the propulsion as well as the steering of the shield in silt, which is governed greatly by the quantity of muck taken sausage-like through the shield.

Further, it is the speaker's opinion that a tunnel structure of reasonable cost in silt has to be flexible during the period of construction, the silt acting on it like a fluid, and the shield demanding that the lining follow it in what is never a straight path. A cast-iron tunnel circle, 23 ft. in diameter in the shield, becomes from 2 to 3 in. greater in vertical diameter, and correspondingly less in horizontal diameter, shortly after the shield leaves it; and, months later, it returns to its original shape. This distortion, in a tunnel of 23 ft. exterior diameter, will not be any less in one of 42 ft. exterior diameter, and in the speaker's opinion, it is not economically practicable to resist it structurally. With cast-iron lining, the plates are more or less free to slide on one another, and the character of the bolting permits further flexibility, though at times a segment is broken without either weakening or endangering the tunnel; with concrete blocks, this inevitable action has also to be borne in mind. Under the land the action is the reverse of that in the silt under the river, and was resisted by turnbuckles and posts.

It is essential that the tunnels be made as water-tight as possible, but it may not be difficult to decide whether this can be done most readily, economically, and permanently with a machined cast-iron structure or a concrete block structure.

The cost of a tunnel is greatly dependent on the speed of construction; practically the same over-all and labor costs have to be borne, whether the rate of construction is 6 or 16 ft. per day. Metal lining can be built very expeditiously by men having comparatively little experience or skill, and it is doubtful if any such performance could be approached with concrete blocks, in this case, because the speaker thinks the behavior of the shield in silt would not be very agreeable to that kind of lining, also in this case. The words "in this case" are repeated because the speaker wishes to see the use of concrete blocks, in shield-built tunnels, where safe and practicable.

Since the Compressed Air Labor Law and the war have greatly increased the prices of labor and materials, the speaker has not made a specific estimate for a tunnel under the North River. However, without apprehended difficulties, and with the assumption that the scheme is feasible, the known increase of difficulties, and the increased market rates of labor and materials, it is the speaker's opinion that the estimate of cost cited is insufficient to cover the plan under discussion.

Mr. Forgie.

The speaker has probably said enough to indicate that, in his opinion, this project of a 42-ft. tunnel requires more study; and that definite opinions cannot be given on this occasion nor in this way; besides, to him it has seemed that, on some matters, the premises are uncertain. The speaker has considered this discussion as informal, and has been pleased to join it in that spirit, though by no means irresponsibly.

Mr. Thomson has referred to the North River tunnels in silt as rising and falling with the tide, as does a floating body. That is the reverse of the case, as tidal rise (load) compresses the ground, and the tunnel, as a part thereof, goes with it, falling with the rise and rising with the fall a very little, as occurs in any ground structure subject to alternations of load. Briefly, in this connection, the tunnel does not move within the silt.

Mr. Parmley.

W. C. PARMLEY,* M. AM. SOC. C. E.—That the time has already arrived when there is pressing need for more ample traffic accommodations between New York City and the Jersey shore requires no argument. As a citizen and taxpayer of New Jersey for many years past, the speaker feels a personal interest in the matter of more adequate communication between the metropolitan center and the districts west of the Hudson River.

The 36-ft. tunnel plan advocated by Mr. O'Rourke certainly appeals to the imagination, and its great traffic capacity is a very compelling argument in its favor, provided the difficulties inherent in a tunnel of this size are not such as to offset its advantages.

The broad water barrier between the States of New York and New Jersey has already been set at naught by the completion of six tunnels, and there can remain no doubt as to the practicability of building more tunnels of approximately similar size and by similar methods; but as the proposed tunnel is nearly double the diameter of bore of any river tunnel yet built, and has nearly four times the area of heading, one wonders whether the difficulties of the kind encountered in the existing tunnels might not become embarrassing in a structure of this size.

The depth below the surface, necessary in order to give protecting cover, would be great, and also the pressures on the completed tunnel and the thrusts required of the jacks to push the shield ahead. In some places the ground is soft, approximating a hydrostatic condition, and at other places, in firmer material, there will be an entirely different distribution of the loads. These variations must be given full weight in the design of the tunnel section, but, before this can be done, it becomes essential to establish limiting relations between the vertical and horizontal components of the earth pressure. This relationship

* New York City.

Mr. Parmley.

also affects vitally the matter of pushing the shield and the ability of the newly erected tunnel lining to withstand the pressures without serious crushing, shearing, or splitting.

The published data in regard to driving the Pennsylvania Railroad Tunnels and the Hudson Tubes furnish important information on this subject. Messrs. Hewett and Brown, in their paper* on the Pennsylvania Railroad Tunnels, state that a number of the cast-iron segments lining the tunnel were broken by the unbalanced pressure of the ground. As this number was considerable (166 as reported), the conclusion is that they were being loaded well up toward their ultimate strength. If this assumption is correct, then, by finding the moment of resistance of the cast-iron lining and comparing it with the pressures and stresses due to earth pressure under different degrees of fluidity, one can deduce, at least, a rough idea as to the probable intensity of these pressures on a tunnel of the large diameter which it has been proposed to build.

As a check against this method of argument, the total thrust of the jacks in pushing the shield with all doors closed has been compared with the total combined weight of the earth and water over the tunnel, thus arriving at a ratio of static resistance of the earth to the total vertical weight. Then, by Rankine's formulas, the corresponding fluidity of the ground has been deduced. Without giving the details of these two calculations, it may be stated that they lead to substantially the same results. That at times the jacks were pushed to their limit is indicated by the statement of Messrs. Hewett and Brown, that the pistons had a tendency to bend, and that it would probably have been better if the diameter of the plungers had been 10 in. instead of $8\frac{1}{2}$ in. Furthermore, some of these same jacks were used for the shield of another tunnel, to which reference will presently be made, and it was found that, on account of bending, all had to be overhauled and re-aligned before they could be used.

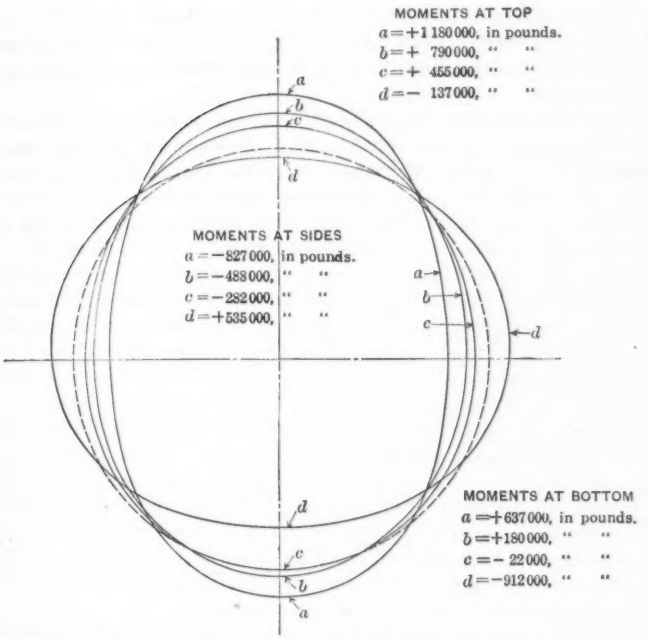
In order to cover a wide range of softness of the earth, the pressures and moments of the 23-ft. Pennsylvania Railroad Tunnels were calculated for headings that would theoretically stand on natural slopes of 3:1, 4:1, 6:1, and 8:1. The last is the condition of hydrostatic pressure.

To shorten the story, Fig. 11 shows the equilibrium polygons for the four cases named, together with the approximate moments at the crown, the springing line, and the invert.

Now, taking into account the axial thrusts, and dividing each of these moments by the section modulus of the cast-iron lining segments at each of the points shown, the approximate stresses in the cast iron, for the different conditions of the earth, have been computed and are shown in Table 2.

* *Transactions*, Am. Soc. C. E., Vol. LXVIII (1910), p. 152.

Mr. Parmley.



APPROXIMATE EQUILIBRIUM POLYGONS FOR DIFFERENT KINDS OF MATERIAL SHOWN, AND FOR AXIS OF TUNNEL RING 39 FT. IN DIAMETER.

FIG. 11.

TABLE 2.—APPROXIMATE TRANSVERSE STRESSES IN CAST-IRON LINING, IN POUNDS PER SQUARE INCH.

Material.	Top.	Sides.	Bottom.
3:1	+ 25 300	− 16 100	+ 13 000
4:1	+ 16 300	− 9 600	+ 38 000
6:1	+ 8 600	− 4 600	+ No tension.
Hydrostatic pressure	− 900	+ 9 700	− 17 900.

Mr. Parmley.

The algebraic signs in Table 2 indicate on which side of the axis the line of pressure comes, the plus sign indicating tension on the inner side of the ring and the negative sign tension on the outer side of the segment.

The different values for the maximum stresses correspond well with the known values for cast iron, but it is interesting to note that those found by A. N. Talbot, Past-President, Am. Soc. C. E., for cast-iron pipes tested by him, which would provide conditions more closely applicable to this case, as they were obtained from curved instead of from straight specimens, ranged from 21 000 to 33 000 lb. per sq. in.

From an inspection of the foregoing results, taken in connection with the actual breakages, it seems plain that the ground has natural slopes of approximately 3 : 1 or 4 : 1, as most of the breaks were in the top of the tunnel, with a few in the invert, indicated by Table 2 as the points producing the most intense stress, and these stresses in turn correspond with the moduli to be expected in the cast-iron segments.

Interest in the hydrostatic condition lies mainly in showing the direction in which the variation of stress travels as the ground becomes more and more fluid. It would also appear that both the vertical and horizontal pressures are functions of the depth, and that the limits of horizontal to vertical intensity probably lie between about 50% for the case of 3 : 1 material, and about 60%, for the case of 4 : 1 ground, results which also agree with values obtained by taking account of the pressures required of the jacks, as already stated.

Although it is probable that the air pressure, due to its drying-up effects on the earth, causes the latter to offer a greater horizontal resistance to the shield movement, and correspondingly less horizontal pressure on the tunnel ring than it naturally does, the error, if any, in both cases, is on the side of safety in these calculations.

It would appear from the foregoing that, including the effect of air pressure it would be necessary to provide ram power equal to the static resistance of earth having a natural slope of 2 horizontal to 1 vertical. This requirement would give to the Pennsylvania Railroad Tunnel shield 3 150 tons, where actually 3 300 tons were provided. In similar manner, the shield of the Hudson Tubes would have required about 1 600 tons, where 2 000 tons were actually provided. Reduced to a square-foot heading basis, the effective push of the jacks in the Pennsylvania Railroad Tunnel amounted to about 8 tons and in the Hudson Tubes to about 9 tons.

The conclusion, therefore, is that in any large-size tunnel, such as is now proposed, because of its greater depth and the increased possibility of encountering denser material, not less than 10 tons per sq. ft. of heading should be provided.

Mr. Parmley.

If this conclusion is justified, one is led naturally to ask the following questions, and on their affirmative answer depends the possible success or failure of a concrete lining in such a tunnel as now proposed.

1st.—In a tunnel of 36 ft. interior diameter, what thrusts and bending moments will the ring be subjected to, and will a 36-in. thickness of ring be sufficient?

2d.—Will the 36-in. ring be able to carry the thrusts of the powerful jacks that it will be necessary to use?

3d.—Will the concrete lining courses be able to resist the shearing and bending produced by the jacks?

In answer to the first question, it may be stated at once, without going into detail, that a 36-ft. tunnel, 3 ft. thick, with 25 ft. of earth and 45 ft. of water above its top, and with earth of a character which gives a horizontal pressure equal to 50%, or less, of the vertical, the crushing and bending stresses on an unsupported ring would be destructive. At the crown the thrust would be about 85 000 lb. per lin. ft. of tunnel, combined with a moment of more than 3 400 000 in-lb. If acting on a plain concrete section, even though no joints occurred at the crown, it would mean a crushing force on the outer edge of the ring of 2 500 lb. per sq. in., and in tension on the inner edge of more than 1 100 lb. per sq. in. The corresponding stresses at the springing line and the invert would also be destructive. More extended calculations for the thrusts and moments at the critical points, for the variations in the character of the ground noted, show that a ring, 48 in. thick and heavily reinforced, would be necessary to meet the conditions safely.

With a ring 36 in. thick it becomes absolutely essential, therefore, that it be supported and fixed at several points by interior walls and floors. Only in this way can the line of resistance be kept near the central line and safe pressures on the concrete be secured. The same statement also may be made regarding a cast-iron segment ring of reasonable thickness.

It should be noted here that the upper horizontal floor, occurring at about the upper quarter points, should be made to act primarily as a tension member, and that additional strength should be given to the inside of the tunnel ring at the crown by suitable reinforcement or bracing. The invert, also, would need similar attention. All points of support for walls and floors must be designed to become effective immediately after the shield is pushed off the block rings, otherwise, destructive effects might be experienced. If, however, these provisions are properly taken, the ring, in so far as these factors are concerned, may be made safe, and the first question may be considered as answered satisfactorily.

Mr. Parmley.

As to the second question, regarding the pressure of the rams on the concrete itself: If a pressure of 10 tons per sq. ft. is used for the 42-ft. heading under consideration, the total pressure becomes 13 800 tons, and this, if distributed uniformly around the center line of the concrete ring, requires 111 tons per lin. ft. of the circumference. If the ring is made up of sixteen blocks, as shown in the published plans for the tunnel, there would be thirty-two jacks of 430 tons each. At a pressure of 5 000 lb. per sq. in., the plungers would be 15 in. in diameter—rather formidable looking affairs, to say the least. They would be 3 ft. 10 in. from center to center around the center line of the concrete ring. Now, if it were possible to distribute this pressure evenly over the entire area of the face of the concrete ring, the pressure on the concrete would still be 520 lb. per sq. in. Such even distribution, of course, is impossible.

If a system of lug contacts between the blocks is used, in order to prevent beam and shear effects, it would be necessary to limit the number of contacts to two per block. These contacts, therefore, would of necessity be of considerable size, or the excessive concentration of pressure would result in splitting and bursting the blocks. To increase considerably the areas of these contacts would result in the same difficulty in distribution as in the case of plain block-to-block contacts; otherwise, bursting concentrations would result. That a large amount of distribution is necessary is evident from the pressure given for the case of complete ideal distribution.

The only adequate way out of the difficulty seems to be to use a series of aligned cores extending through the body of the blocks from front to back, and against which each jack may re-act directly. These cores can be made of high resisting material, slightly longer than the width of the blocks, so as to operate loosely through the blocks, or, they may be manufactured in the blocks and retained therein by frictional means. They may be made of a rich mixture of cement inside a heavy steel hooping, or completely encased in iron pipe. In this way a compressive resistance of 5 000 lb. per sq. in., equal to that of the jacks, or even more, could easily be secured. They would have the advantage that any crushing effect would not affect the block proper, and need not throw any strains on the blocks, due to irregularities in their position in the ring.

They can also be made with a small cap at the end, of weaker material, which will crush and thus automatically give the needed distribution of pressure over the end of the core. They may also be made to serve most effectively to pin and lock the blocks of one ring to those of the adjacent rings, as the contact of core to core can readily be made to occur either between the rings or within the body of the block itself.

Mr. Parmley.

A further and very great advantage of the core method lies in the possibility of applying four instead of only two jacks to each block. With fixed bearing surfaces, it is not possible to use more than two contacts to the block, because that would imply absolutely perfect bearing of ring to ring, but, if the cores are used to transmit the reactions independently of the ring blocks, the number may be increased to any extent desired.

With four jacks per block, the number is increased to sixty-four, and the diameter of each is reduced to 10½ in., with a maximum of 215 tons per jack. These jacks would now be more in line with the sizes already used, and the fact that the cores may be permitted to slip in the blocks and adjust themselves would permit equalization of the pressures and result in a completely interlocked lining, sound and suitable to withstand its proper burden. The second question, therefore, may be considered as answered in the affirmative, if these precautions in the design of the ring are taken.

Taking up the third question, in regard to shearing stresses, it is obvious that the shear which otherwise would be sustained by the blocks is now transferred wholly to the cores. That this precaution is absolutely essential may be shown by a simple calculation.

Suppose there is a ring of blocks, 36 in. thick and 18 in. wide, or a sectional area of 648 sq. in. per ring of block tunnel. Consider a block lining in which the longitudinal joints are broken. In the absence of perfect bearing of block against block along the entire length of the circumference, one of the jacks bearing on the block will act against an overhanging end of one-half the length of the block, thus setting up both bending and shearing stress in it. A 430-ton pressure would thus give a mean shear over the cross-section of the block of 1 380 lb. per sq. in. It is thus evident that the block would fail, either in bending or shear, almost before the jack had been adjusted to its serious work.

On the other hand, by using suitable cores, the shearing stresses in the block can be practically avoided, and, in so doing, it is also relieved of bending stress.

A statement was made in a New York paper of March 16th, 1919, to the effect that the use of concrete blocks would be experimental, as this method had never been used before. This statement is in error. Sewer tunnels of concrete block construction, designed by the speaker, and costing hundreds of thousands of dollars, have been built with entire success, and have been substantially water-tight. The new water-works tunnel at Cleveland, Ohio, costing upwards of $1 000 000, with which the speaker was connected in a consulting and constructing capacity, was built successfully with reinforced concrete blocks. It is 10 ft. in inside diameter and is built of rings of reinforced blocks 11 in. thick. The length of the tunnel is about 15 000 ft., and its

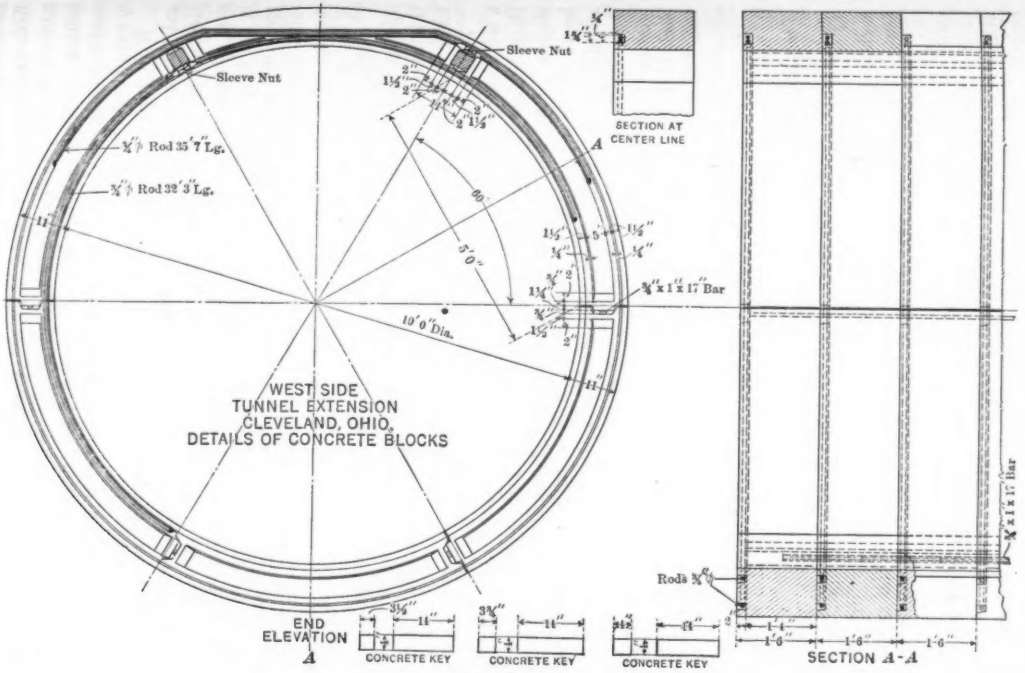

FIG. 12.

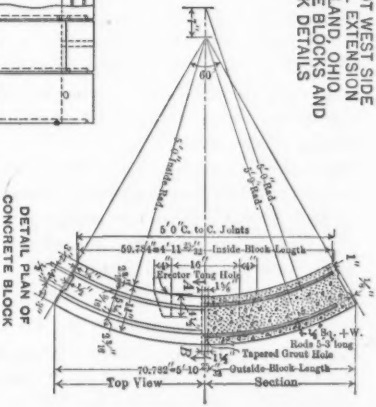
DETAIL PLAN OF CONCRETE BLOCK



Mr. Parmley.

center is about 95 ft. below the surface of Lake Erie for the entire distance. Therefore, it carries a burden of from 40 to 50 ft. of soft clay and sand overhead and about 50 ft. of water, for its entire length.

For most of the work, an air pressure of from 15 to 25 lb. was used, and the shield, which was about 12 ft. 2 in. in diameter, was driven forward by twelve 8½-in. jacks, which, at 5 000 lb. pressure per sq. in., gave a thrust of about 137 tons each, or a total of 1 650 tons. The speaker believes that they were never driven to their limit. In order to start the shield, about 3 000 lb. pressure was used, but, as soon as it moved, the pressure was reduced, and only about half as much was necessary to maintain the forward movement.

At a pressure of 3 000 lb. per sq. in., and considering full and ideal distribution of pressure on the block ring, a thrust of about 430 lb. per sq. in. against the concrete blocks was developed. Of course, it was impossible to get this ideal distribution. Part of the tunnel was built with continuous longitudinal joints, and part with the longitudinal joints broken.

At the pressures mentioned, some spalling of the blocks resulted, and, in the portion laid with longitudinal joints broken, there was still more spalling, and a number of blocks were sheared. It is evident that, if the jacks had been worked to their limit, considerably more damage to the blocks would have resulted, even with the best distribution of the pressures possible by means of wood blocking.

It was the behavior of concrete blocks under jack reactions, as thus actually observed, and the damages resulting, which convinced the speaker that, in order to insure the success of concrete block lining for this undertaking, it will be essential to take the precautions which have just been discussed.

Whether the tunnel is to be a single barrel of large dimensions, divided up for the different roadways, or twin tunnels of smaller diameter, it will be necessary to take such precautions, but, if they are taken, there seems to be no reason for not using a concrete block lining with entire success and safety, without involving the large expense of cast-iron or cast-steel segments. The tunnel can be made water-tight by the grouting process. Its construction involves the entire elimination of one major process—the cost and erection of the cast-iron segments—and the concrete in the blocks will be of a far higher quality and uniformity than can be obtained in practice where the concrete is deposited in mass within the tunnel.

Mr. Thomson.

T. KENNARD THOMSON,* M. AM. SOC. C. E.—Not one, but several, tunnels should be constructed between New York and New Jersey.

The ventilation can be easily taken care of; but separate compartments should be provided for foot passengers and horse-drawn vehicles, and for fast and slow motors.

* New York City.

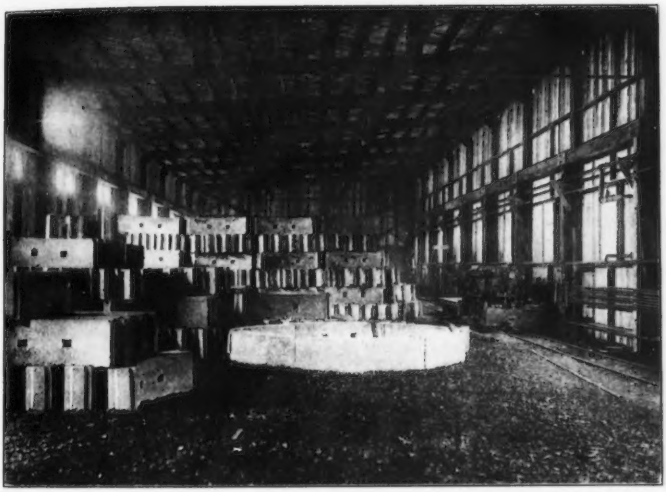


FIG. 14.—CONCRETE BLOCKS FOR LINING CLEVELAND WATER SUPPLY TUNNEL.

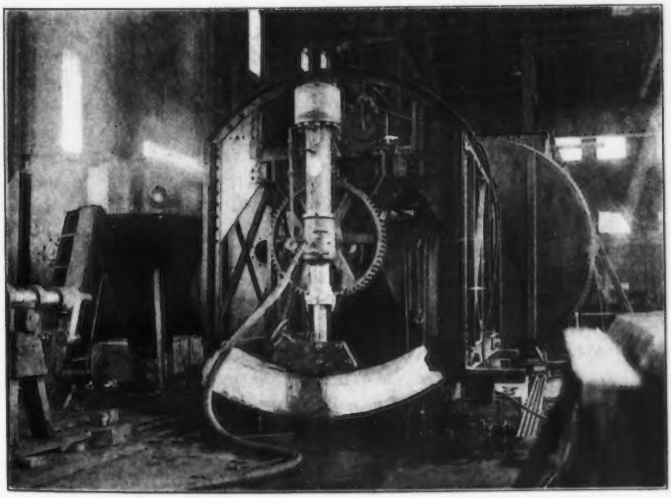

FIG. 15.—MACHINE FOR SETTING CONCRETE BLOCKS FOR CLEVELAND WATER SUPPLY TUNNEL.

Mr. Thomson

The first requisite for a tunnel should be safety; the second, permanence; and the third, economy.

A shield-driven tunnel under the Hudson River does not, and will not, comply with any one of these three requirements, as compared with what can be done by the trench method. The reason for this is that the Hudson River silt is about 200 ft. deep, and any tunnel in it must perforce be a floating tunnel. For, if its weight is made just right without any live load, it will be too heavy with trains or vehicles in it. In short, it is a physical impossibility to design a tunnel which would always be in equilibrium. As a matter of fact, the Pennsylvania Tunnel, probably the best lined tunnel in the world, rises and falls inversely as the tide.

James Forgie, M. Am. Soc. C. E., in a remarkably complete monograph* on this tunnel, has given a very good description of the value of this silt for bearing purposes. He explains that the shield, 23 ft. in diameter, could have been driven across without excavating any material whatever, except for the difficulty of keeping the tunnel in its proper location, so, as a matter of fact, from 30 to 60% of the material was excavated, and the rest was squeezed out of the way. Who would ever think of building a house on material that could be squeezed so easily? He states, further, that the tunnel itself was subject to distortion when a second tunnel was being driven alongside.

Now, a tunnel that rises and falls inversely as the tides, as perforce any tunnel must which is shield-driven through this material, would be likely sooner or later to get a water-jacket around it, and, if this ever happened, a catastrophe might result, as the tunnel lining, as usually built, would not stand much tensile strain, especially in a longitudinal direction.

The proposed concrete blocks would not be nearly as strong as the lining of the Pennsylvania Tunnels, which is composed of heavy cast iron with 2 ft. of concrete.

Surely it would be better to construct a tunnel which would always be rigid and in a state of equilibrium, and would remain permanently where put. This can be done easily by the open-trench method, that is, by dredging a channel and driving an ample number of foundation piles, so that the tunnel could never sink any lower, and then make the tunnel so heavy that it could never rise, and so wide that it could never bend. It could be built on the surface, like a boat, with bottom, sides, and roof of reinforced concrete, say, 6 ft. thick. It could be in lengths of 1 000 ft. or more, and when ready could be towed into position and easily sunk on the piles. An air chamber could be provided below it, in order to permit any additional excavation, if desired, after the section had been sunk.

* *Engineering News*, February 28th, 1917, p. 228.

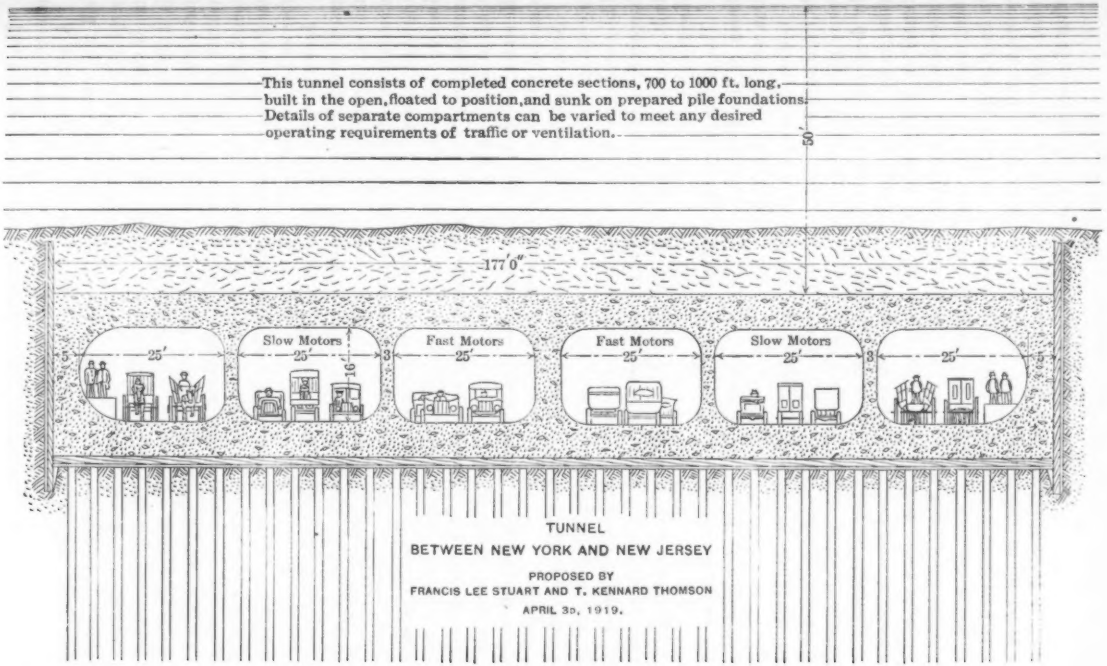

FIG. 16.

Mr. Thomson.

There are many ways of making the joints between the sections after they are in position, but the speaker's method would be to sink pneumatic caissons over the joints. Mr. Thomson.

The proposed 42-ft. tunnel has two compartments, one for each direction. That means that horses and fast and slow motors going in one direction would all travel in one compartment, thus preventing real speed. The trench method would permit of six compartments, each larger than those proposed for the shield-driven tunnel. In this way horses, slow motors, and fast motors would be separated from each other by walls of concrete 3 ft. thick.

Obviously, a trench tunnel can be placed at a higher level than a shield-driven tunnel, especially in such fluid material, thus shortening the approaches by 1 000 ft. or more, which is a great advantage. Such a trench tunnel, Fig. 16, is proposed by Francis Lee Stuart, M. Am. Soc. C. E., and the speaker, and would have three times the capacity of the shield-driven tunnel, without costing any more to construct, and be safe beyond peradventure of a doubt, as no shield-driven tunnel ever can be without going to unheard of expense.

F. Lavis, M. Am. Soc. C. E.*—This discussion has been very interesting. There can be little doubt that it is desirable to establish communications between New York City and New Jersey by means of a vehicular tunnel, or even several of them. The question of design, however, needs serious consideration, and the speaker does not believe that this is the place to decide the merits of the various proposals. The salient points which affect a decision as to the proper design have already been pointed out, and the speaker does not intend to go into that matter further. Mr. Lavis.

Mr. O'Rourke's section has many features to commend it, if it can be built, but it certainly is a most serious matter to commit the future of an enterprise like this to a type of construction which presents so many serious difficulties of execution, and which has not been tried out in some way.

It is a long time since the speaker has had anything to do with actual tunnel construction, and he is inclined to look at all these matters from the standpoint of people who are asked to provide the money for various enterprises. He is inclined to think, therefore, that if the construction of a vehicular tunnel to New Jersey were to be carried out by private enterprise, there would be, to say the least, a great deal of hesitation in making a commitment, involving some $12 000 000 at the lowest estimates, with so many uncertainties involved.

Of course it is realized that, if no one had ever ventured into the unknown, there would never have been any shield-driven tunnels, or much of anything else, and the speaker does not wish for a moment to say that Mr. O'Rourke's scheme cannot be carried out. It is realized,

* New York City.

Mr. Lavis. also, that it is not altogether the same to advocate the expenditure, in some cases, of public money to aid in the progress of the Arts and Sciences; so that the use of public funds for the purpose cannot be put on exactly the same basis as the use of private capital.

Just at the present moment, however, in view of the tremendous demands for capital all over the world, demands which will exceed the supply for so many years in the future that we cannot see the end, it behooves every one to be rather more conservative than usual. At any rate, if the section proposed by Mr. O'Rourke is so much more desirable than others, if the cost of its construction—in case of the success of his scheme—is thought to be enough less than others to warrant it, the logical thing to do would seem to be to make the experiment, at least on a large enough scale to determine its feasibility, before commitment to the whole enterprise.

Now, aside from the merits of one scheme or the other, there is the proposal of Mr. Brown that this meeting should decide the matters of controversy. The speaker does not think it is at all the function of this Society as such, or of the meeting, to advise any one on a proposed engineering project relating to civil affairs. During the war all have given their time and services to the Government, inf so far as they have been required, but, in a matter of this kind, which is one of ordinary civil and commercial life, the speaker would suggest that it is a proper subject for a properly appointed commission of qualified engineers, who should be paid for their services and for their knowledge. The camouflage of the word "reconstruction" ought not to cover the giving of engineering advice gratuitously to the Government—Municipal, State, or National.

Mr. Tomkins. CALVIN TOMKINS,* ASSOC. AM. SOC. C. E.—Transportation between New York and New Jersey is the crux of port organization in New York City. It is not a local problem, but extends from New York City to Albany, for, with the exception of one bridge of insufficient capacity (that at Poughkeepsie), there is no all-rail crossing. The consequence is that, to the already congested lighterage transfer at the Port of New York, there is added the large transfer of continental business between New England, Canada, and the remainder of the United States. In some way improved all-rail communications between these parts of North America must be secured, and thus avoid the convergence of the congestion at the Port of New York. For passenger service this has been accomplished with the tunnels of the Pennsylvania Railroad, and now the same thing must be done for freight.

The vehicular tunnel project is commendable as a first step toward solving the freight problem, but it still involves the necessity of breaking bulk in New Jersey and the transfer of freight by truck or lighter to New York City. That, indeed, is better than the present

* New York City.

Mr. Tomkins.

method of effecting transfers between New York and New Jersey, but it necessitates the continuance of the railroad terminals in New Jersey, and, on that account, is not economical. In addition, a vehicular tunnel will only provide for service to Manhattan; it will not reach to Long Island, except across the bridges.

For motor truck traffic the tunnel is all right, but the all-rail connection is needed, not only with Manhattan, but across that Borough to New England and to connect with the Canadian Railroads. In other words, if New York City is to obtain the greatest port advantages possible, there must be done for freight what the Pennsylvania Railroad has done for passenger transportation. The vehicular tunnel project is welcomed as a step in the right direction, but only as a beginning.

When the railroad tunnels for freight have been completed, the conditions in New York City will be comparable to those which obtain at every other port in the world. The port is unique in being divided into two parts by the Hudson River barrier, which necessitates an immense transfer by floating equipment. This caused the coal famine in 1917-18, and is responsible for the strike in 1919, because the nice adjustment of the intricate floating machinery can easily be made unworkable by labor disturbances.

This great floating transfer must be abolished. Every other port in the world is accessible from all sides by railroads which lead to those ports, and such railroads can be made to connect with each other and with the docks, warehouses, and factories by a loop system of terminal railroads. Everywhere, except only at the Port of New York, this kind of railroad terminal distribution is in operation. Since the war placed the railroads under one administration, correct railroad integration has been established at all United States ports except only New York. At that port the Government is now largely in control of the transfers by water, and much of the former friction and expense incident to private separatist control of equipment has been done away with. When the Long Island and New Jersey systems are connected, and, incidentally, Manhattan is connected with both, freight can be transferred cheaply and advantageously from one side of the harbor to the other.

The steamships, factories, population, and wealth, are, for the most part, on the east side of the port, and the greater part of the railroad terminal system of the country is on the west side. The two parts must be joined, and thus make transportation a continuous process.

Let this tunnel project, then, be regarded as the first important step toward a complete union of the two sides of the port, which will make New York like other great seaports and remove from it the unenviable distinction of being the worst organized of the large ports of the world.

Mr. Schaeffer.

AMOS SCHAEFFER,* M. AM. SOC. C. E. (by letter).—It is not clear why a tunnel 42 ft. in diameter should be built, even if it is possible to do so. All the economies which are claimed for a tunnel of this size could be applied to one of smaller diameter. Practically all the quantities will be greater for one large tunnel than for two small ones. The shield will weigh more and cost more to build, the quantity of material to be excavated will be greater, and the quantity of concrete for the block lining will be greater. As the number of points of attack for two smaller tunnels would be greater, and the material would be handled through double the number of shafts and by double plants, two tunnels could be driven much more rapidly than one of the larger size.

Therefore, estimates of cost, as between one large tunnel and two small ones, should be based on the use of the same materials. If it is practicable and economical to use concrete block lining in the large tunnel, it is likewise practicable and economical to use it in the smaller tunnels. On this basis, two smaller tunnels, without doubt, could be shown to cost less than the larger one.

It is not intended to enter into a discussion on the merits of concrete block lining, but simply to point out that if its use is practicable in one case it is in the other, and, therefore, that it is unfair to compare the cost of a large tunnel lined with concrete blocks with that of two smaller ones lined with cast iron.

The capacity of the proposed tunnel is greater than necessary for the present needs of traffic and those of the immediate future. It provides for two levels, with three lines of travel moving in the same direction on each level. A capacity of 100 000 vehicles per day is claimed. From the best information available, this estimate is based apparently on the following rates of speed and distances apart of vehicles:

3	miles	per	hour,	50	ft.	apart.
9	"	"	"	60	"	"
15	"	"	"	80	"	"

These assumptions require a 24-hour day to provide a capacity of 100 000 vehicles.

It is believed that at least two of these assumptions need revision, in order to make a determination of the maximum capacity. A 12-hour day is the longest that should be used as the time basis. It is well known that traffic will not use a highway to its maximum capacity for 24 hours continuously.

In view of the distance within which motor vehicles, moving at various rates of speed, can be stopped by the application of brakes, the spacing of vehicles can be reduced.

A horse-drawn vehicle, moving at the rate of 3 miles an hour, can be stopped within a distance of a very few feet. Motor vehicles moving

* New York City.

at the rate of 9 miles an hour can be stopped within a distance of 9 ft., and those moving at the rate of 15 miles an hour can be stopped within a distance of 21 ft. With a margin of safety of not less than 100%, these spacings can safely be reduced to 30, 40, and 60 ft., respectively. Mr. Schaeffer.

On this basis, with the same rates of speed, and a 12-hour day, the maximum capacity of a tunnel with six lines of traffic would be 37 000 vehicles in one direction, or 74 000 in both directions.

It has been assumed that, at the completion of the tunnel, say, in 1922, 4 000 vehicles per day would use it in each direction, or 8 000 in both directions. This would be only about one-ninth of its capacity. The Commission assumes an annual increase in traffic of 5 per cent. This rate of increase was used undoubtedly more to show the small amount of traffic which would produce sufficient revenue to pay the interest, amortization, and maintenance charges than to indicate the traffic which could be expected.

On the assumption that traffic would increase at the rate of 8% per annum, there would be 37 160 vehicles using it per day in 1942, or 20 years after its completion, which is still only one-half its maximum.

It would seem, therefore, that a tunnel with a diameter of 42 ft. is probably considerably larger than is needed at first.

Two tunnels with a capacity for two lines of traffic, traveling at the rate of 3 and 9 miles per hour, and with 30 and 40 ft., respectively, between vehicles, would have a maximum capacity for a 12-hour day of about 41 000 vehicles in both directions, which is five times the capacity required at their completion, and would be ample for the traffic in 1942, 20 years after their completion.

It is admitted, of course, that six lines of traffic in three tunnels will not give as large a capacity as six lines in one tunnel on two levels, but it is believed that the smaller cost of two tunnels and the postponement of the construction of additional tunnels until they are needed, will largely compensate for this.

There is still another, and perhaps the most important reason, for constructing two smaller tunnels instead of a large one, namely, traffic conditions in Manhattan.

With the experience which New York City has with traffic, the concentration of six lines of vehicles moving in opposite directions, within a small area, cannot be considered good planning, unless there are overwhelming reasons for it, such, for example, as the provision of additional roadways on the East River bridges, where the cost of construction to support the dead load is so much in excess of that to support the live load that the cost of providing for additional lines of traffic is relatively small.

In tunnel construction by the shield method, the cost of providing for additional lines of traffic will be more nearly in the ratio of the additional facilities.

Mr. Schaeffer.

With the entrances and exits as close together as they are shown on the plan, there would undoubtedly be confusion of traffic on account of its movement in opposite directions and congestion on account of its volume within a small area.

This objection can be overcome by locating the entrances of the smaller tunnels a block or two apart. If future tunnels are needed, it would be preferable to locate their entrances some distance from those already constructed on both shores. It is not conceivable that all traffic would have Canal Street, Manhattan, or 12th Street, Jersey City, as its objective points. Traffic, therefore, would be served very much better if additional tunnels were built at some point farther up the river, say, at about 14th Street.

In the latter part of 1915 the Police Department took traffic observations at street intersections at more than 200 points in New York City. This count showed a traffic ranging from 29 200 vehicles in 10 hours at Columbus Circle, to 7 000 vehicles in the same time at Madison Avenue and 59th Street.

In 1908, the north- and south-bound traffic on Fifth Avenue at 42d Street was 8 945 during a period of 10 hours, and, in 1916, it was 16 860 for the same time, showing an increase of 90% in 8 years. As everybody is familiar with the congestion of traffic at this point, these figures will serve as a measure of traffic at other points.

The traffic which may be expected to use the tunnel in 1942 has been estimated at 37 160 vehicles, which is exclusive of the normal traffic which will use the streets at and about the entrance to the tunnel. This is more than double that which existed on Fifth Avenue at 42d Street in 1916 and is only 50% of the capacity of the tunnel. In other words, the construction of a tunnel of the capacity proposed would create a congestion of traffic greater than that for the removal of which the city is at present expending approximately more than $625 000 in the construction of the ramp at 34th Street and the Viaduct between 40th and 42d Streets on Park Avenue. These improvements are made primarily to provide a thoroughfare on Park Avenue for the purpose of relieving congestion of traffic on Fifth Avenue. Before the full benefits from this improvement can be derived, it will be necessary to acquire the right to use the roadway around the easterly side of the Grand Central Station, which was formerly Depew Place. It is estimated that the cost of acquiring this right and making the necessary changes will involve an additional sum of $625 000, or a total of $1 250 000.

It seems inconsistent, therefore, to create a condition, at large expense, in one part of the city for the removal of which large sums are spent in another. It would seem that there are abundant reasons, aside from the structural uncertainties in a large tunnel, which indicate the construction of smaller tunnels than the one proposed.

Mr. Tratman.

E. E. R. TRATMAN,* ASSOC. M. AM. SOC. C. E. (by letter).—With reference to the accommodation to be provided in the proposed Hudson River Tunnel for vehicular traffic, it appears to the writer that more attention should be given to that for pedestrians. Although no large amount of pedestrian traffic may be expected in a tunnel of such length, there are special conditions and emergencies to be considered. For instance, there is the possibility of a vehicle breakdown or blockade, causing passengers to leave cars or omnibuses and start to walk out of the tunnel. If a blockade should be attended by an accident, such as a collision or the burning of an automobile, there is the further possibility of a panic or a rush for escape. None of the plans appears to provide adequately for such contingencies.

In the proposed 31-ft. tunnel section, with two sidewalks on opposite sides of the upper deck roadway, the available width of these walks is limited materially by the overhead curve of the tunnel wall, as the sidewalk level is slightly above the center line of the tunnel. This would cause people instinctively or necessarily to keep near the curb. As a matter of fact, it does not seem that two people could walk side by side or pass each other without inconvenience.

In the Blackwall Tunnel under the Thames, at London, the sidewalk level is about 4 ft. below the center line, so that the tunnel wall curves outward from the walks and there is ample overhead clearance. This is also true of the Rotherhithe Tunnel, with its greater diameter and greater width of sidewalks. It is not easy to understand the reason for the inner curb or footguard on the sidewalks, which forms a part of the lining in these two tunnels. It reduces the effective width by a few inches, although every available inch is desirable. In fact, the capacity and convenience of the walk might be increased by flattening the curve of the tunnel lining for the height of a few inches above the walk, thus increasing the actual width. This would not affect the strength of the tunnel.

In the proposed 42-ft. section for the Hudson River Tunnel, the single depressed footwalk appears to be inconvenient and inadequate, with the further objection that dust and dirt from the roadway are likely to be scattered over the pedestrians. The plan for a multiple-tube concrete tunnel also shows scant accommodation for pedestrians, although the designers note that details of the compartments can be varied to meet requirements.

Ventilation of the different levels and compartments will be a special problem in such a long tunnel having traffic composed largely of motor vehicles, and in which the vehicles will occupy so high a proportion of the cross-sectional area of the compartments. For instance, in one design the high-speed compartment has a headway of 9 ft., while the height of the highest vehicles is said to be 7 ft. 10 in.

* Wheaton, Ill.

Mr. Tratman. Dilution by forced draft would seem to be necessary, probably in combination with an exhaust or induced draft.

About a year ago, it was proposed to extend a street across a Chicago park by means of a tunnel, in order to avoid cutting the park by a surface thoroughfare. One question was in regard to ventilation conditions with a heavy traffic of motor vehicles. The writer made some inquiry as to conditions in the two Thames Tunnels at London, but the motor traffic was so slight, comparatively, that pollution of the atmosphere from that cause was a very small factor. Apparently, those tunnels have provision for artificial ventilation, but this is not in operation. Further, the cross-sectional area is much larger in proportion to that of the vehicles, than is the case in the proposed designs for the Hudson River Tunnel.

The double-deck tunnel idea is of particular interest to the writer for the reason that about 1890 or 1891 he undertook to suggest such an idea to the late Sir Benjamin Baker, Hon. M. Am. Soc. C. E., then Consulting Engineer for the proposed Blackwall Tunnel under the Thames. An oval section was proposed, with a diaphragm or upper deck for the roadway and a narrower bottom deck for pedestrians. Naturally, the reply was to the effect that for a tunnel in loose material nothing but a circular section could be considered. It may be noted, however, that railway tunnels of oval section in swelling and unstable material have been reinforced in some cases by steel ribs. This treatment, of course, was only designed to meet unexpected emergencies and is not a criterion for tunnel design, while the railway tunnels in question were of much smaller section than would be required for a double-deck tunnel.

Supplementing the double-deck oval section, the writer suggested a circular tunnel having an upper deck supported on columns and not in contact with, or in any way connected to, the tunnel wall, thus avoiding any interference with distribution of stresses in the latter due to external pressure. In other words, there was a viaduct within the tunnel. It should be explained that neither of these ideas ever attained the dignity of a serious study as to its possibility or practicability.

Paper No. 1435

WATER SUPPLY FOR THE CAMPS, CANTONMENTS, AND OTHER PROJECTS BUILT BY THE CONSTRUCTION DIVISION OF THE UNITED STATES ARMY*

By Dabney H. Maury†, M. Am. Soc. C. E.

With Discussion by Messrs. George W. Fuller, P. H. Norcross, Clarence Goldsmith, T. Kennard Thomson, W. P. Mason, J. Waldo Smith, E. T. Thurston, K. M. Boorman, William J. Boucher, Morris Knowles, H. F. Dunham, George A. Johnson, F. R. Harris, Maurice R. Scharff, Samuel A. Greeley, Lynn E. Perry, Asa E. Phillips, and Dabney H. Maury.

Synopsis.

This paper presents briefly some facts in connection with the organization of the Construction Division, giving credit to those civilians who were principally responsible for the selection of its personnel and for the preparation of the form of contract adopted. It then describes the general standards for the water supply systems of the cantonments and the preparation of the typical preliminary plans, giving an illustration of the manner in which time was saved by the latter.

The preparation of general plans for the distribution system, and the scheduling of materials therefor, are next described and illustrated, and studies of the various water-supply problems are outlined. The paper next sets forth the general specifications and the construction details for water supply, and illustrations of the latter are presented.

* Presented at the meeting of April 2d, 1919.
† Lt.-Col., Quartermaster Corps, Construction Division, U. S. A.

The scheduling and purchase of service pipe materials and of supplementary materials are explained, and the conditions governing the selection of the various materials used are stated.

Under the heading "Sanitation", credit is given to the Sanitary Corps of the Medical Corps for its cordial and efficient co-operation from the very beginning to date, and to the Supervising Engineers, the Engineers for the Contractors, and the Sanitary Officers assigned to the camps, for their excellent work in looking after the quality of the temporary water supplies during the construction period.

Additional sanitary precautions insisted on by the office of the Advisory Engineer for Water Supply are stated. The methods by which water-works materials for the National Guard camps were shipped to these camps in advance of plans, and in most cases in advance of the arrival of engineers, contractors, or working forces, is narrated.

The enlargement of the scope of work of the Construction Division is mentioned, and a number of working plans for water-works are presented and described.

The paper states the consumption of water in the camps and the methods adopted to check leakage and waste, and also the changes in the National Guard camps and the manner in which water supply materials were made available for these changes before such changes had been authorized.

The preparation of contracts for water supply extensions and for water service, and the rates at which water was furnished to the Government, are next treated.

Finally, the paper represents a summary of the work done and of the results accomplished in First Cost, Sanitation, and Fire Protection, and gives credit to all those who bore a responsible part in the work, whether in the office or in the field.

ORGANIZATION.

Much has been written about the remarkable achievements of the Construction Division of the Army, and no man who served in that Division, in no matter how humble a capacity, can fail to be proud of having been connected with an organization so notably efficient.

It would be unfair to praise the Construction Division, however, without first giving credit to the men who were not thereafter officially

connected with it, but who in the very beginning helped to select the major part of its official personnel and to mobilize its contractors, and who collaborated with the Office of Cantonment Construction in the preparation of a form of contract absolutely different from any that had ever been used on Government work, but which has been proved to be the only form which could have produced the desired results.

The list of the men, to whose energy, ability, practical patriotism, and wise counsel the country owes so much, included, among others, Messrs. Morton C. Tuttle, Leonard Metcalf, George W. Fuller, William O. Washburne, Frederick Law Olmstead, Asa E. Phillips, and Col. William A. Starrett.

In those crucial early days in April, May, and June, 1917, after it had finally been decided that the United States should prepare to do its part in the greatest war of history; when practically no army was available and there was no place to train one; and when every additional day's delay in getting troops to France meant the loss of many more lives and vast treasure, these men spent weeks in Washington doing work of incalculable value to the country, and without other recompense than the joy of serving.

When the writer was "telegraphed" into service on May 28th, 1917, the work of these men had begun to show results. The Office of Cantonment Construction, starting with a personnel of 10, already numbered 40 or 50, and the men who were lucky enough to be selected were racing in from all parts of the country to take up their duties. In October, 1917, the number had increased to 700; in March, 1918, to 1 400; and when the Armistice was declared, on November 11th, 1918, the force in the Washington office alone numbered 2 800, and about 25 000 more, scattered all over the United States and its insular possessions, were reporting to Gen. Marshall, Chief of Construction Division, which number did not include any of the 200 000 laborers or other employees of the contractors.

The day before the writer's arrival in Washington, Clarence Goldsmith, M. Am. Soc. C. E., Hydraulic Engineer of the National Board of Fire Underwriters, had reported to the Officer in Charge of Cantonment Construction. The services of Mr. Goldsmith had been generously donated to the Government by the National Board of Fire Underwriters up to April 6th, 1918, when he was commissioned a Major in the Quartermaster Corps. From May 28th to date he has been Prin-

cipal Assistant to the Advisory Engineer for Water Supply. His loyalty, untiring energy, and exceptional ability, as a designer of water-works and fire protection systems, have saved millions for the Government.

During the period of construction of the Cantonments and National Guard Camps, no further increase was made in the personnel of the Office of the Advisory Engineer for Water Supply, the services of such assistant engineers, computers, draftsmen, or stenographers as were required being supplied from the general offices of the Construction Division. In the latter part of 1917, the number and diversity of the problems submitted to the office necessitated the organization of an additional and independent force. The members of this force were, without exception, active, industrious, and faithful, and to every one of them the writer desires to give credit for work well done, and to express his grateful appreciation of their loyal co-operation.

General Standards.

In all water-works designed by this office, the first consideration has always been the sanitary quality of the supply, of which more will be said later. This being assured, the first point to be determined in the actual design of the water-works system was the quantity of water required. This was basic, and entered into every part of the design.

It was necessary to provide a supply sufficient, in the practical operation of the cantonment, for every reasonable requirement of the troops, for domestic use, as well as for proper fire protection. The restrictions and limitations included the following: the limited appropriations; the enormous prices of material and labor; the difficulty of obtaining on short notice as much of either as would be required for the simultaneous construction of sixteen camps to house about 40 000 troops each; the necessity of avoiding, in so far as possible, the use of steel or iron, both of which were urgently needed for ships, guns, and munitions; and, above all, the absolute necessity for haste.

It was early recognized that some leakage and waste would be unavoidable; at the same time it was believed that the concentration of most of the water fixtures in lavatories, where from forty to seventy outlets could be inspected almost at a glance, and the fact that, under military discipline, proper administrative rules could be enforced,

would combine to make it an easy matter to reduce leakage and waste to relatively small quantities.

More consideration was given to the determination of the proper allowance of water than to any other question, and Leonard Metcalf, and George W. Fuller, Members, Am. Soc. C. E., collaborated with this office in the consideration of this important and fundamental subject.

After the quantity of water required for domestic consumption had been determined, the question of fire protection was studied, and the requisite quantity and the pressure at which this quantity should be available were also determined.

Typical Preliminary Plans.

The broad and general engineering standards which should govern the construction of the water systems to supply the camps having been determined, the next most important problem was the preparation of such plans for the individual systems as would require the minimum time for construction, utilizing such material as would not hamper the progress of shipbuilding and other vital war industries, and at the same time would furnish safe, adequate, and reliable service.

Typical plans of the building layouts of the several units of a standard divisional cantonment were prepared by the Camp Planning Section and transmitted to this office, as were also typical plans showing various methods in which these several units could be grouped on the ground. It was manifest at the outset that no particular arrangement of units could be adhered to for all the camps, as the grouping would necessarily have to be governed in each case by the topography of the camp site. It was possible, however, in almost every case, to adhere strictly to the group plan of buildings in each of the several units, and this permitted the preparation of standard plans showing the location of mains, and the location and sizes of the service pipes in each unit.

Fig. 1 is a typical plan of the mains and service pipes in a Regimental Unit. The lengths and sizes of the mains, and their location outside the limits of the individual units, were governed in each case by the topography, which dictated the way in which the units were strung together, and also by the point at which the water supply was delivered to the camp.

Plate VIII shows several typical arrangements of water distribution mains, corresponding to various groupings of the units in a Divisional Cantonment. In one case the units are strung out in a single line, with the supply coming in at one end; in another, with the units strung out as before, the supply comes in at the center; and, in the third case, the units are grouped in horse-shoe form. This latter arrangement was the ideal one, as it gave an opportunity to loop the mains across the ends of the horse-shoe, which greatly reduced the friction losses and enabled smaller mains to be used.

In the preparation of these typical plans, studies were made to determine in each case the economic location and sizes of the mains, gates, and fire hydrants, so that, by the time the first rough plan showing the approximate actual grouping of the units on the ground in any particular camp was submitted to this office, it might be possible, with the minimum of delay, to specify offhand the sizes and the approximate lengths of mains required and to place orders for the bulk of the water-works materials.

As an instance of the way in which time was saved by this method, the case of Camp Lewis may be cited. It had been decided to build a cantonment near American Lake, Washington, but two local factions had been unable to agree on the proper location, and Maj., afterward Col., Peter Junkersfeld,* of the Building Division of the Construction Division, was sent out to settle the matter and fix the final location of the camp. On the day after his arrival, he sent a telegram which read as follows:

"Refer Government Maneuver Map No. 69. Follow railroad southwesterly from American Lake to Dupont Station. Draw line easterly from this station to point midway between Spray Lake and Spray Farm. This line is the center axis of camp, which is in typical horse-shoe plan with open end eastward. Source of water supply, wells and springs between American Lake and Sequalitchew Lake. Site for reservoir, Hill No. 320; actual elevation, 390. Engineering Division wire sizes and lengths of water mains required."

This telegram arrived at the Washington office just before midnight, and within two hours the Engineering Division wired the information required, which information enabled the pipe for the distribution mains of the camp to be ordered immediately from the nearest Pacific Coast fir pipe manufacturers. A few hours thus sufficed to settle a basic question in connection with a cantonment more

GENERAL NOTE

The number and arrangement of units will, of course, vary for each cantonment, and it is likely that in no case will they correspond closely to this plan. It is important, however, that the location of water mains and hydrants, with regard to each unit in each cantonment, should follow closely the layout shown hereon. No matter how much it may be necessary to alter the positions of the respective units, or to curve the mains between them, the mains should run straight across each unit, and in the positions shown on this plan.

FIG. 1.

than 3 000 miles away. Although the location of this camp was not definitely decided until after June 28th, the camp was ready for troops on September 1st.

PLANS OF DISTRIBUTION SYSTEM AND SCHEDULES OF MATERIALS.

The City Planners and Engineers on the ground at each camp sent in as fast as possible topographic maps of each camp site, on which were shown the general arrangement of the several units; and as soon as this general arrangement was approved by the Camp Planning Section, a blue print was furnished to this office. The locations and sizes of the water mains, fire hydrants, valves, and other accessories were immediately drawn on these blue prints with red pencil; from these red pencil marks the necessary materials were scheduled, and the schedule was sent to the Materials Division for purchase. The blue print with the red marks on it was then sent back to the Drafting Room of the Camp Planning Section, where it was traced as a water-works drawing, and given its proper number. Blue prints from these tracings were forwarded to the camps, but the method of handling the work in this office actually enabled most of the water supply materials to be shipped to the camp before the plans arrived.

Fig. 2 shows the water distribution system for Camp Funston. The supply was from wells, low-lift pumps at which delivered water into surface storage at the pumping station, whence it was pumped through the distribution mains and into elevated storage on the hills on the other side of the camp. This arrangement gave an ideal system, as the elevated reservoirs furnished a second source of supply, and their location on the opposite side of the camp greatly reduced the friction losses in the mains. It will also be noted that there are duplicate supply mains from the pumping station as well as from the reservoirs; that the distribution mains are looped everywhere; and that there are no dead ends.

Fig. 3 shows the water-works layout for Camp Grant, which embodies many of the same features as that for Camp Funston, the principal difference being that at Camp Funston the near-by hills enabled wood-stave tanks to be used for storage, and at Camp Grant the flat topography compelled the use of the more expensive steel tank on a steel tower.

Fig. 4 shows the arrangement of mains and service pipes for a typical base hospital unit. The presence of the corridors connecting

all the buildings made it difficult to furnish effective fire protection to the hospitals; first, because they eliminated fire-breaks and offered a fine chance for a fire to spread from one building to another; and, second, because they blocked access for the fire fighters to the interior

courts between the corridors and the buildings. To offset these disadvantages, as much as possible, all hospital groups were given duplicate supply mains, the distribution mains were very thoroughly looped and gated, the hydrant spacing was made unusually close, and, wherever possible, openings were left under the corridors at strategic points.

Studies of Water-Supply Problems.

The foregoing describes more particularly the method of procedure in regard to the distribution system, which naturally formed the larger part of the water-works construction. The selection of the source of

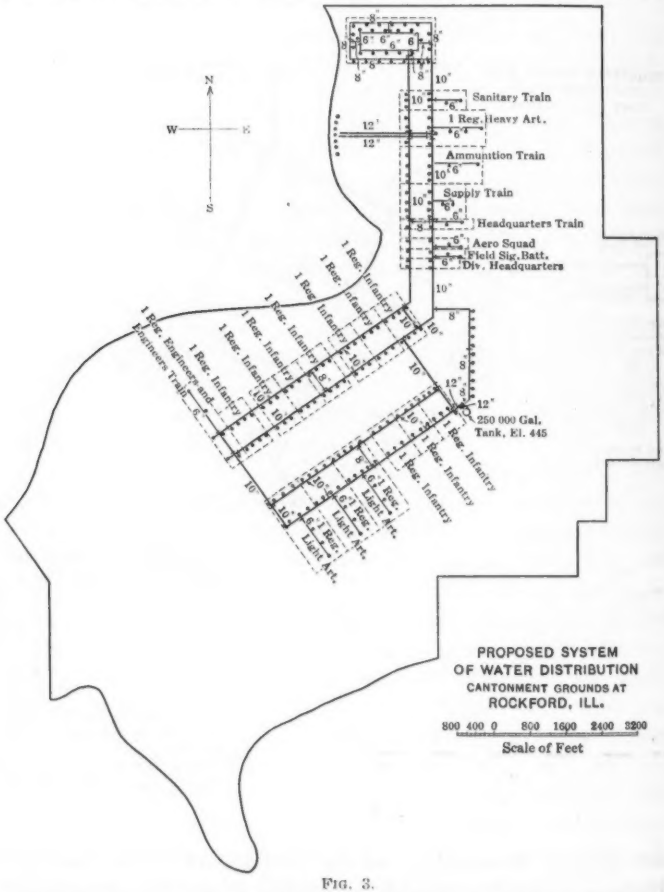

Fig. 3.

supply, the determination of the method of bringing it to the camp, and the planning of pumping stations, purification works, or reservoirs, if any or all of these were required, were usually governed largely by

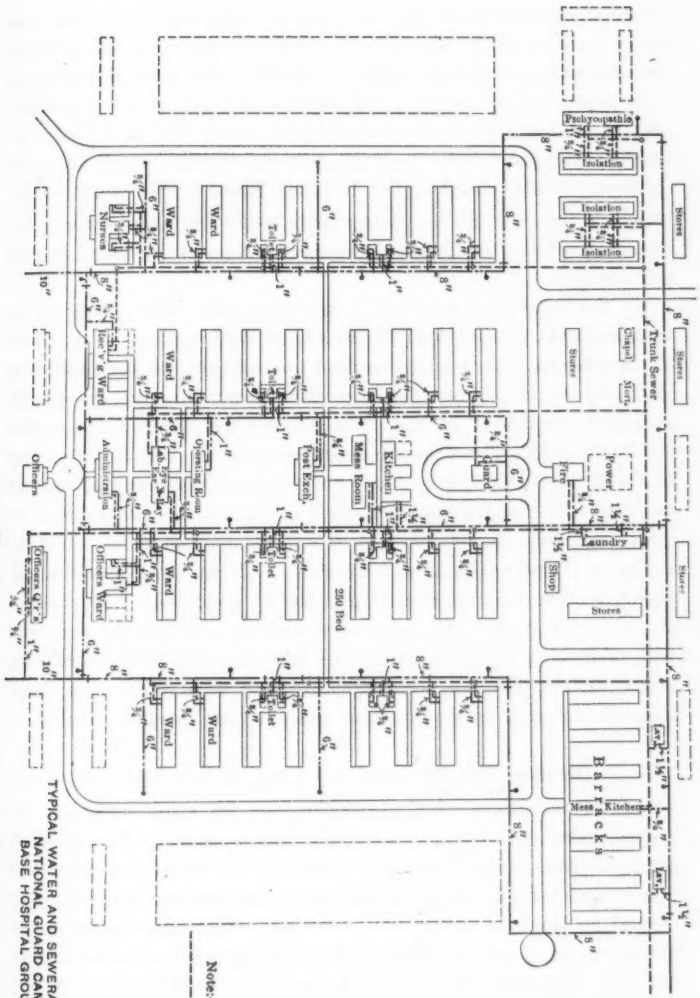

FIG. 4.

information conveyed in the reports of the supervising engineers from the camps themselves. Each of these problems was dealt with as fast as the necessary information became available. In some instances, the information was already at hand, either as a result of previous knowledge of the local water supply conditions on the part of the engineers in this office, or in the form of previous reports. Quite often the excellent reports, issued by the National Board of Fire Underwriters, on cities from which the camp supply might be taken, made immediately available most of the information required in regard to such city supplies.

In the beginning, of course, it was impossible, with no data and no time available, to send detailed plans from Washington, and the efforts of the office were necessarily confined to impressing on the supervising engineers at the camps the necessity of adhering to the general standards established by the office, leaving the details to be worked out in the field. These men included many of the very best engineers in the United States; but it was quite natural that any engineer not familiar with the reasons which had controlled the establishment of these standards, should approach the problem much as he would the design of a metropolitan water system, and plan for capacities sufficient to take care of normal growths in population over a period of 20 or 25 years. As opportunity offered, conferences were held with these supervising engineers, at which the reasons for the adoption of the various standards were explained, and these conferences almost invariably cleared up the situation and produced excellent results.

General Specifications and Construction Details.

In the meantime, general specifications for water supply to the cantonments, and typical construction details showing the method of setting valves, valve boxes, and hydrants, of connecting wood-stave pipe to cast-iron pipe or specials, of making connections between mains, of making bends in mains, of connecting service pipes to mains, the arrangements of pipe connections to pumping stations and reservoirs, etc., were prepared and sent out, as well as a schedule of service pipe materials necessary for each individual unit in a cantonment.

Fig. 5 is a diagrammatic layout used in planning the piping connections at pumping stations and reservoirs. The duplication of suction and discharge mains, and the location of gate-valves and check-

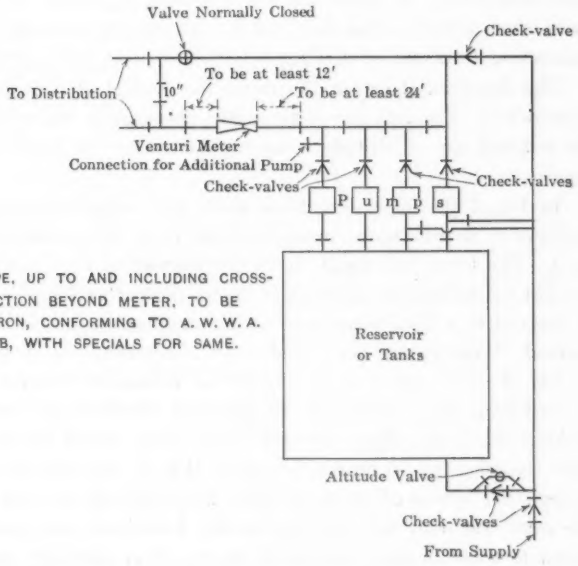
TYPICAL LAYOUT OF PUMPS, RESERVOIR, TANKS, METER AND PIPE CONNECTIONS, FOR WATER SYSTEMS IN WHICH SUPPLY IS DELIVERED INTO STORAGE AND HAS TO BE PUMPED THENCE INTO THE DISTRIBUTION MAINS, AND WHERE THERE IS NO ELEVATED STORAGE ON DISTRIBUTION MAINS. WHERE THERE IS SUCH ELEVATED STORAGE, THE NUMBER OF PUMPING UNITS MAY BE REDUCED.



WHERE PUMPS DO NOT TAKE SUCTION UNDER HEAD, PROVIDE SUITABLE PRIMING APPLIANCES IN DUPLICATE.

WHERE EXCESSIVE PRESSURES MIGHT OTHERWISE COME ON MAINS, AS THE RESULT OF SHUTTING OFF DRAFT WHILE PUMPS ARE RUNNING AT HIGH RATES, SUITABLE RELIEF VALVES SHOULD BE PROVIDED AT PUMPING STATION.

FIG. 5.

valves, make it impossible for the failure of any one valve to put more than two pumping units out of commission, or for the failure of any pipe or special casting to put more than one unit out of commission. Attention is called to the by-pass around the Venturi meter and to the arrangement of the altitude valve on the line supplying the reservoir.

In Fig. 6 are three construction details, the one in the upper left corner showing a bend in a wood-stave pipe line, with two 45° ⌊'s and a length of cast-iron pipe on each side to prevent blow-off. The lower left detail shows a typical connection between existing and new wood-stave mains, by which the use of a cross is avoided. Crosses are more often defective than tees, and the failure of a cross puts all four connecting lines out of service.

The detail on the right illustrates the method of connecting altitude valves. The full size of the outlet check gives free outflow, and the reduced size of altitude valve saves money. The bends facilitate repairs.

In Fig. 7 the upper left detail shows the method of connecting a hydrant to a wood-stave main, and the short 4-in. hydrant branch used. The lower left detail shows the connection of branch lines to wood-stave mains; the upper right shows the connection of a hydrant to the end of a 6-in. wood-stave main; and the lower right shows the method of protecting valves and valve boxes from injury by traffic.

Fig. 8 shows the lead joint used for connecting wood-stave pipe to cast-iron pipe, valves, or fittings, and describes the method of making the joint. When the first orders were placed for wood-stave pipe the office was definitely informed that it was common practice to lead the tenons of the wood pipe into standard cast-iron hubs in the same way that cast-iron spigots are leaded in; but reports soon began to come in from the camps to the effect that this was by no means an easy thing to do. A great many methods were suggested for making these joints, but by far the best of all was that shown on Fig. 8, the idea for which was suggested at about the same time by Mr. Ramsey, Water-Works Engineer for Morris Knowles, Incorporated, Supervising Engineers for Camp Meade, and by an engineer for a camp in the Middle West. The success of the method depended largely on having all the tenons made small enough to provide proper lead space, and on having the diameter of the tenons accurately

FIG. 8.

standardized. The details of the plug and the dimensions of the tenons were worked out by the office with the company which furnished most of the wood-stave pipe, and the other pipe-makers soon agreed to make their tenons of the same dimensions.

Fig. 9 shows, on the left, the method of frost-proofing service pipes under the floors of buildings, the intention being to provide a double air space around the pipe. It was sometimes difficult to prevent the construction forces from defeating the purpose of the device by filling these air spaces with saw-dust or other material, which, when wet, destroyed the non-conducting value of the air space. The details on the right of Fig. 9 show two methods of connecting service pipes to wood-stave mains.

Service Pipes and Fittings.

An estimate of quantities of the service pipe and fittings required for the National Army Cantonments was prepared as per Table 1 (Plate IX), which shows in its upper half the service pipe material required for each unit of each type in a divisional cantonment. The total service pipe material required for each of the sixteen cantonments is shown in the lower half of Table 1, and was readily determined when the number and type of units in any cantonment were once known.

Supplementary Schedules of Materials.

After detailed plans, based on the general plans and specifications, were worked up by the supervising engineers in the field, they would submit, as fast as possible, additional schedules of materials which might be required to complete the work, and these schedules were forwarded to the Materials Division for the purchase of the material, as soon as they had been approved by this office. To expedite the work still further, blanket authority was given in certain cases to the construction forces to purchase, without further reference to Washington, limited quantities of such specified classes of materials as could best be purchased in that manner, instead of through the usual channels.

Conditions Governing Selection of Materials and Equipment.

It may be interesting to note at this point that it was usually possible to deliver water, from the source of supply which had been selected, into storage at the camp. This storage was generally at such

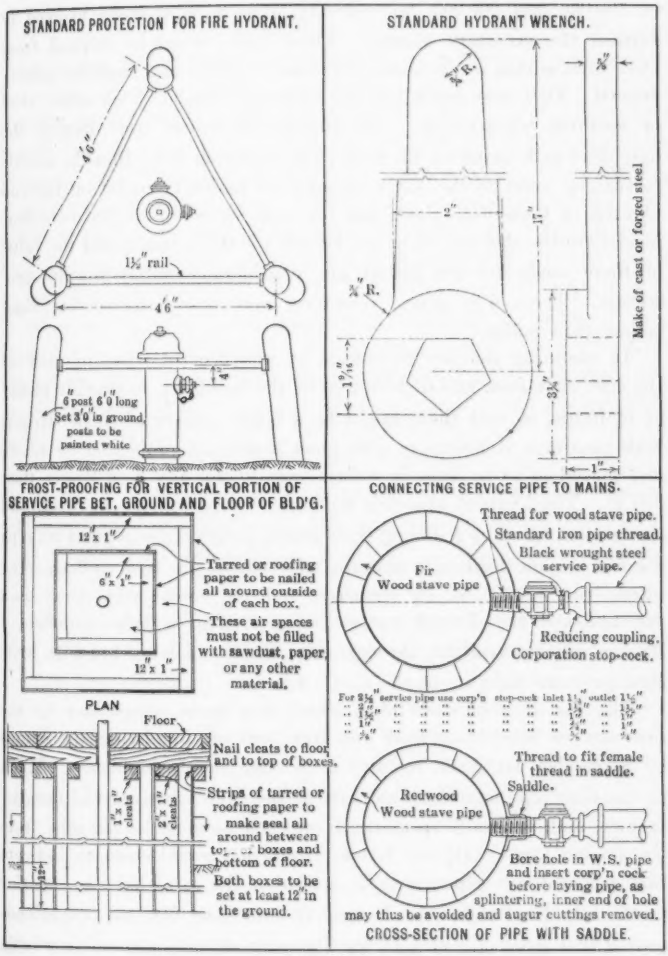

FIG. 9.

an elevation that the pressure available was sufficient for the domestic needs, and booster pumps were provided, where necessary, to raise the pressure and increase the volume available during the times of peak load and during fires. In order to conserve steel, redwood tanks of 100 000 and 200 000 gal. capacity were in most cases utilized to furnish the necessary storage. These tanks could be shipped from California within a few hours of receipt of order, and could be quickly erected. They cost much less per gallon of capacity than either steel or concrete construction. All distribution mains were looped, the only dead ends being on the 6-in. pipe extending down into the corrals to furnish water to the water troughs. A hydrant was set on the end of each of these 6-in. pipes, but the only structures in the neighborhood were the skeleton sheds or shelters for the animals, and the value of these sheds did not justify any considerable outlay for fire protection. These 6-in. pipes, therefore, were essentially service pipes rather than mains.

In planning the fire protection it was deemed wise, in view of the size, character, and distribution of the buildings, to provide plenty of hydrants, so that there might be a large number of small streams with pressures sufficient to give good horizontal projection or reach, and placed so as to make it unnecessary to use any hose longer than 300 ft. The hydrant branches themselves were only 18 in. long, and the friction saved by reducing their length justified the use of 4-in. pipe for the branch, feeding a hydrant with two 2½-in. hose outlets. The nozzle tips were ⅞-in. in diameter, and the combination thus used accomplished the desired purpose of providing a large number of streams quickly available through short lengths of hose, and with first-class pressure right up to the nozzle tip.

The use of wood-stave pipe, which was made compulsory by the necessity of conserving steel and iron and of completing the camps by September 1st, 1917, resulted in a large saving of money. Much of the pine pipe manufactured east of the Mississippi proved unsatisfactory, and, generally speaking, it was not as good as the pipe from the Pacific Coast. Of the latter, experience would seem to indicate that redwood was superior to fir, and that the air-dried was superior to the kiln-dried redwood. Having in mind the fact that experience proved that wood pipe of good quality, properly laid, showed very little leakage, and that the life of such pipe, thus laid, may safely be taken

at about 20 years, it would have been wise, in the writer's opinion, to use this pipe for the camps, simply on account of the saving in cost and time of delivery, even had there been no restriction on the use of cast-iron and steel pipe.

SANITATION.

Although the importance of having the water supply completed by September 1st, 1917, demanded the utmost speed, the question of the sanitary quality of the supply was never overlooked. This office constantly kept in touch with the Sanitary Corps of the Medical Corps of the Army, and there was at all times the fullest possible co-operation with the officers of that corps. Whenever there was the slightest suspicion of danger of pollution, the office that discovered it first immediately informed the other, and both then united in a determined effort to remove the danger.

Great credit is due to the supervising engineers, as well as to the engineers for the contractors, and to the sanitary officers assigned to the camps, for the efficient manner in which they safeguarded the purity of the temporary water supplies used during the construction period.

In addition to the care exercised by this office in the selection of the source of supply, and in purifying the water wherever necessary, particular stress was laid on the following sanitary precautions:

(*a*) The covering of all storage reservoirs in order to prevent accidental or intentional pollution and the formation of algæ;

(*b*) The furnishing of chlorinators to all cantonments or camps, even when the supply might be regarded as normally safe;

(*c*) The prohibition of the use of wells in shallow strata on inhabited water-sheds, or in any other stratum or location in which it might be possible for the wells to become contaminated;

(*d*) The absolute prohibition of any distribution mains carrying polluted water, whether for fire protection, or industrial, or any other use; and of any outlet or fixture from which such water might be drawn; or of any arrangement that would permit the later introduction of any such outlet or fixture. This ruling was often difficult to enforce, but it was always insisted upon.

The results accomplished by the careful consideration thus given to water-works sanitation have been discussed in the technical press.*

The inoculation of the troops for typhoid and para-typhoid by the Medical Corps greatly reduced, but did not entirely remove, the danger of their contracting these forms of water-borne diseases. There was no inoculation against other water-borne diseases, and civilians were not usually inoculated at all.

Water Systems for National Guard Camps.

The work on the water systems of the sixteen National Army cantonments had only fairly commenced when it was decided, late in June, 1917, to construct sixteen tent camps for the National Guard troops. The Construction Division was ordered to have five of these camps ready to take troops by August 1st, five more by August 15th, and the remaining six by September 1st. The difficulties of the problems incident to this new construction were enormously increased by the fact that the orders for water-works materials required by the cantonments had so exhausted the available stock and overtaxed the capacity of the various manufacturing plants that it was impossible for them to furnish any considerable quantity of similar materials within the time allotted for the construction of the National Guard camps. Therefore, it became necessary to use, in so far as possible, materials which had not hitherto been drawn upon. After a conference with prominent representatives of the manufacturers of wrought-steel pipe, it was decided to use 6-in. wrought-steel pipe for the distribution mains for eleven of these tent camps, to use 6-in. cast-iron pipe for the two camps which were in the Birmingham district, and to use 6-in. redwood stave pipe for the two camps in California and the one at Deming, N. Mex. The steel companies rolled and shipped 500 000 ft. of 6-in. steel pipe in a little more than 6 working days. The cast-iron pipe manufacturers shipped about 80 000 ft. of 6-in. cast-iron pipe within a not much greater period, and the wood-stave pipe manufacturers made correspondingly good deliveries of their product; so that a considerable part of the necessary material was on the way to the camps, in some cases before any constructing quartermaster, supervising engineer, or contractor, was on the ground, and in practically all cases before any plan showing the topography of

* Editorial in *Engineering News-Record*, April 18th, 1918, entitled "Our Military Camps Show Remarkable Typhoid Fever Record."

the camp site was available. In this matter, as in all others in which the Materials Branch of the Construction Division had a part, the efficiency of that branch was splendidly demonstrated.

Enlargement of Construction Division Activities.

As the National Army and National Guard camps neared completion, work was begun on Camp Hill and Camp Stuart, near Newport News, Va.; Camp Merritt, at Tenafly, N. J., and Camp Johnston, near Jacksonville, Fla.; the first three being embarkation camps and the last a school of instruction for quartermasters. Camp Meigs, in Washington, was also built at about this time, and then began the work of building warehouses, terminals, munition depots, arsenals, plants for the manufacture of gas, bag-loading plants, proving grounds, and all the other projects entrusted to the Construction Division, the field of activities of which was enlarged to include all construction work for the Army in the United States and its insular possessions.

The construction of the embarkation camps marked a change in the size and grouping of the buildings in each unit, and the typical layout of water mains was changed to suit the new building plans, the principal change being the use of three lines of mains, instead of two, through each unit. This resulted in still better fire protection, and in a great reduction in length of service pipes.

Some Typical Working Plans.

The personnel in the office having been enlarged at about this time, it became possible to prepare drawings in much greater detail, and the office was thus enabled to make plans showing much more clearly than formerly the arrangement of pumps, motors, and piping, in or near the various pumping stations or reservoirs.

A drawing of this sort could be turned out in a very few working hours by the specially trained men in this office, and these drawings invariably saved a great amount of labor in the field. Furthermore, these layout plans, which were sent to each job with the manufacturers' detailed foundation plans for the motors, internal combustion engines, and pumps, prevented serious mistakes on the part of the construction engineers, who, although unquestionably competent in many other lines of work, were naturally often more or less unfamiliar with the special field of water-works design, and were so fully occupied with

their construction work that they could not give the time for the development of carefully studied plans.

The plans shown on Fig. 10 are for a filter plant and pumping station of very small capacity, and are reproduced here more because

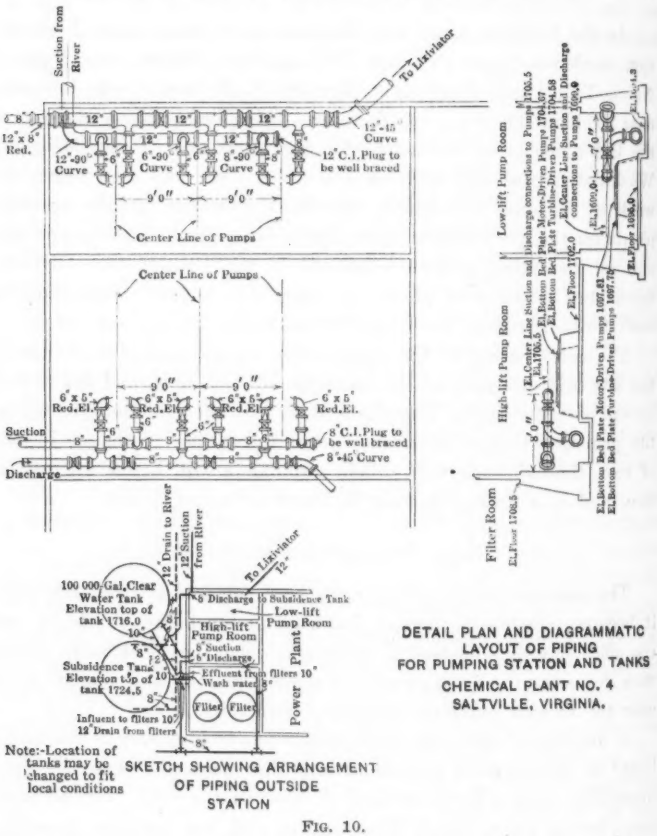

FIG. 10.

the plant was an unusually complete one than for any other reason. It will be noted that there was a small sedimentation tank, two filter tanks, a clear-water tank, and three low-lift and three high-lift pumping units. It was the practice to eliminate from plans of this sort all unnecessary lines, or dimensions, or lettering, but to indicate what-

FIG. 11.

ever was shown so clearly that the drawing could be easily understood by the men in the field.

Fig. 11 shows plans for the pumping station, storage tanks, motor-driven pumps, gasoline-engine-driven pump, and piping and connections. In this case the supply came from a city main, the water from which flowed into the first of two wooden tanks, each having a capacity of 200 000 gal. The pipe connections were arranged so that the first tank was always kept full, the second tank being filled only by the overflow from the first one. In this way there was always at least 200 000 gal. of storage for fire purposes, in addition to whatever storage might happen to be in the second tank, which took care of the peak loads due to domestic use, and, in addition, also to such supply as the city mains might be capable of delivering to the suction of the fire pumps. The small pumping unit was utilized to keep the small sprinkler tank full at all times.

The pumping station and tanks shown in Fig. 12 were for fire service only. The supply in this case was from wells, and the ordinary domestic pressures carried were more than sufficient to fill the two 200 000-gal. tanks adjacent to the pumping station, so that there were always at least 400 000 gal. in reserve for extinguishing fires. There were two electrically-driven and one gasoline-engine-driven centrifugal fire pumps, taking their supply from the tank.

Fig. 13 shows plans for pumping station and tanks, in which it will be noted that there are two 200 000-gal. storage tanks near the surface, and a 75 000-gal. elevated steel tank. The supply was taken from the city mains, the pressure in which was sufficient to fill the low storage tanks, but not always sufficient to put water in the elevated tank; and a booster pump was provided to fill the latter and give the necessary domestic pressure. In case of fire the two fire pumps could take their supply from the two 200 000-gal. tanks, supplemented by such water as might come in from the city's mains.

It will be noted that practically all the regular service pumps were motor-driven centrifugals. These were operated, as a rule, by purchased current. Steam machinery and electric generators could not be had, whereas electric motors and centrifugal pumps were obtainable on reasonably short notice, and the combination made the cheapest of all pumping units. At least one internal combustion engine was usually provided as a reserve against a break-down in the electric service.

GENERAL LAYOUT OF FILTRATION PLANT
CAMP A. A. HUMPHREYS
VIRGINIA.

The first of these features was the arrangement of the mixing chambers and sedimentation basins. It will be noted that there were two sedimentation basins, each of which had a baffle-wall extending from the pumping station building toward the far end of the sedimentation basin. The two mixing chambers, one for each basin, were just inside of the rear wall of the building and near its center. The coagulant was added to the water in these mixing chambers, and the water in each basin then flowed away from the building around the end of the baffle-wall and back again to an effluent chamber similar to the mixing chamber, and likewise enclosed within the walls of the building. Large windows in the rear wall of the building provide abundant light over the mixing and effluent chambers, and it is thus possible for the filter operator, without leaving the building, to study, side by side, the influent and effluent water, and thus obtain an excellent idea of the way in which the floc is forming. This is a feature which has always appealed strongly to every filter operator.

Another somewhat unusual feature of the design of this plant is the open pipe gallery, which has the same advantages over the usual dark and concealed pipe gallery that open has over concealed plumbing.

In addition to the wash-water pumps, there are three electrically-driven and one gasoline-driven centrifugal pumps, all in the same main room as the mixing and effluent chambers, filter tanks, operating platform, and pipe gallery; and the whole plant is thus about as compact and accessible as it would be possible to make it.

The illustrations accompanying this paper show less than 1% of all the water-works plans prepared in the Washington office. They were selected for reproduction because they gave a fair idea of the general character of the work done. It should be noted, however, that none of the larger projects is shown, the plans for these being so large that they could not well be reduced to a scale suitable for reproduction in this paper.

Consumption of Water.

The determination of the quantity of water to be supplied to the National Army camps has already been mentioned. The specifications provided that the water-works systems should be capable of furnishing at all times at least 55 gal. per capita per day. This included an allowance of 15 gal. apiece for the horses and mules. As there was

about one animal for every three men in a divisional unit, the net allowance per man was 50 gal. per day.

This is about 80% more water than was supplied in the British, French, Belgian, Canadian, or German cantonments, and is larger than the quantity recommended by Capt. Francis C. Harrington.*

It is a well-recognized fact that Americans use, and waste, more water than any other nation; but there are many cities in the United States, where meters are in fairly general use, and in which the average daily per capita consumption is less than 50 gal., including all water wasted, leakage in mains and service pipes, water for flushing sewers, sprinkling lawns and streets, public and private fountains, the water used by the Fire Department, and all sorts of industrial, commercial, and manufacturing uses, these latter being often quite large in quantity; in fact, every drop of water that enters the distribution mains at the pumping station.

The experience of the Construction Division with the Army camps proves conclusively that the allowance of 55 gal. per capita per day to such camps was a very liberal one. A little study will show that it would be almost impossible for any man to use legitimately more than 20 to 25 gal. per day, and that all water used in excess of this quantity must represent leakage and waste. It is impossible to stop all leakage and waste, but it ought to be, and is, easy in such camps to keep the total consumption down to twice the maximum legitimate quantity actually required by the men.

When the sixteen National Army camps were first occupied there were only a few of them in which the consumption of water exceeded 55 gal. per capita per day, and in several cases the daily per capita consumption was less than 40 gal. At this time there was practically no check on the use or waste of water, as the utilities organization had not yet been perfected. Furthermore, it was not then possible to secure effective utility management, by reason of the fact that the utilities officers had to report to the Camp Quartermasters, which meant that they were under the Commanding Officer at the camp. As the chief interest of these Commanding Officers was to train troops for France, they were quite naturally not always willing to furnish the utilities officers with a sufficient personnel of non-commissioned officers

* In his paper on this subject, published in *Professional Memoirs*, Corps of Engineers, Vol. 8, No. 39.

and enlisted men to maintain the utilities in proper operating condition and to check leakage and waste. During the severe winter of 1917-18, the daily per capita consumption increased greatly in most camps, and in some instances exceeded 100 gal. This was due partly to leaks in plumbing, but largely to the fact that water was allowed to run to waste to prevent freezing. In the four most northerly camps, which had central heating systems, the water used for heating was not returned but was blown to waste, and the water wasted in this manner alone amounted to 600 000 gal. per day per camp during cold weather. By the end of the winter the utilities organizations in each camp had begun to attain their stride and make their influence felt, their efficiency being increased enormously by the fact that they were now reporting to the Maintenance and Repair Division of the Construction Division, instead of to the Commanding Officers at the camps.

In the early summer of 1918, orders were sent to the Commanding Officers at every Government activity, instructing them to co-operate in every way possible with a view to checking leakage and waste of water. The effect of these orders was soon apparent, and at practically all the camps the daily per capita consumption was reduced to less than 55 gal. without the slightest inconvenience or shortage of water for any one. As time permitted, the utilities officers, working under the direction of the Maintenance and Repair Division of the Construction Division, conducted water waste surveys and made frequent inspections and repairs of plumbing. This work not only greatly reduced the waste of water, but showed conclusively that the excessive consumption was due almost entirely to waste and to leaky fixtures, and that the underground leakage was almost invariably negligible.

Changes in National Guard Camps.

When the National Guard camps were originally laid out there were no barracks, the men being quartered in tents; and there were no sewerage systems. This meant that there was no necessity for providing either the same standards for fire protection, or the same quantities of water, as were called for by the National Army camps, an allowance of 30 gal. per capita being ample for them. Nevertheless, in laying out the distribution systems for these camps, the possibility that they might ultimately have sewerage systems, and that they might have to be converted from tent camps to barrack camps, was not over-

looked, and the two lines of 6-in. distribution mains running through each unit in the camp were laid along the outer edges of the units and in such manner that, later, should the changes just referred to be made, the water supply systems could be quickly brought up to the standards then required by laying an additional main of larger size through the center of each unit.

Early in 1918, the officers in charge of the Construction Division foresaw the probability of improvements in the National Guard camps. No orders for such improvements had been issued, however, and no funds were available. The one thing that seemed certain was that, when the orders did come, the changes would have to be made in a hurry. With a view to being prepared to reinforce the distribution systems in the Guard camps with the least possible delay whenever the order should come, this office endeavored to arrange some plan by which the necessary redwood pipe might be manufactured and shipped from California to some advantageously situated eastern point from which immediate deliveries could be made to the various National Guard camps. Unfortunately, however, there was no authority for any such action.

After nearly two months had passed in fruitless efforts to perfect the arrangement just referred to, that plan was abandoned, and it was decided to place an order for 300 000 ft. of redwood stave pipe of assorted sizes for the account of a large Quartermaster terminal project which had been recently authorized and the funds for which had not yet been drawn upon to any great extent. It was the intention to have the pipe actually made and shipped to this Quartermaster terminal, and thereafter to divert it, either in transit, or by shipment from the Terminal, to the various camps, to the account of which it could then be charged.

In the meantime plans were prepared in this office for the reinforcing of the distribution system and for such other changes in the water supply systems at the camps as might be rendered necessary by their conversion from tent camps to barrack camps and by the introduction of sewerage systems.

In August, 1918, this office was ordered to prepare immediately estimates of the cost of the changes in the water supply system of twelve National Guard camps, incident to the changes previously referred to; and with the plans for these changes already prepared, the office

was able to deliver the estimate required within two hours. Practically none of the pipe ordered for the account of the Quartermaster terminal, but actually required at the National Guard camps, ever reached the terminal. At the time of the shipment of this pipe the freight congestion on the railways was greater than ever before in the history of the country, so that it took from 6 weeks to 2 months to deliver pipe from the Pacific Coast to points east of the Mississippi River. A very serious delay was avoided in the manner just described.

Contracts for Water Service and for Extensions.

In a great many instances the water supply for the Government activities was taken from existing water-works systems which were owned either municipally or privately. In all such cases, special contracts had to be made for water service, and whenever the quantity of water desired was large, it was almost invariably necessary to embody in the contract for water service provisions for extensions to the existing plant, in order to enable it to meet the increased demands.

It was usually impossible for the owners of the existing system to finance the desired improvements, and these contracts, therefore, provided that the Government would make the required extensions and turn them over to the Water Department for operation as soon as they were completed. The contracts also provided that, within a certain reasonable time after the termination of the war with Germany, the owners of the existing plant should purchase the extensions from the Government on terms which fully recognized the fact that the extensions were made as a result of the emergency occasioned by the war. The interests of the owners of the existing water systems were thus fully and fairly recognized.

As a general rule, the rates paid by the Government for water service were unusually low, especially in view of the enormously increased cost of furnishing the supply. In practically every instance the rate at which water was sold to the Government was the lowest on the local schedule, and in many cases the Government rate was made lower than the lowest schedule rate, a condition which was usually justified by the fact that the Government was the largest local consumer. So far as the writer's recollection serves him, there was no large Government

activity which paid in excess of 15 cents per 1 000 gal., this rate being paid in one instance for water which had to be pumped three times, filtered, and chlorinated. The lowest rate paid for water was 4¼ cents. In many instances the rate was less than 8 cents.

A number of contracts were drawn in which other departments, such as the Navy, the Shipping or the Housing Corporation, were jointly interested with the Army; and these contracts involved negotiations with the several departments, as well as with the owners of the existing water systems.

Summary.

The office of the Advisory Engineer for Water Supply, Construction Division, has handled for the various branches of the Government, water supply problems on more than 275 different projects, involving the construction, in round numbers, of nearly 1 100 miles of mains from 6 to 30 in. in diameter; 700 miles of service pipes from ¾ in. to 2½ in. in diameter; 650 000 000 gal. per day in pumping capacity; 67 000 000 gal. in capacity of concrete, steel, or wood reservoirs or tanks; 3 000 000 000 gal. capacity in impounding reservoirs and more than 40 000 000 gal. daily capacity of filters.

In an article prepared by the writer* late in 1917, the following statements were made with reference to the cost of the water-works systems for the sixteen National Army Cantonments:

"It may also be stated that the cost of reproduction new of the average water-works system in a city of 40 000 inhabitants, at present prices for materials and labor, and exclusive of service connections, would average over $2 000 000, or more than $50 per capita. As nearly as can be ascertained at present, the cost of the water-works of the 16 National Army cantonments, including service connections to within 5 ft. of the buildings, has been less than $11 per capita, or say about one-fifth as great as the reproduction cost new to-day of the average municipal water-works system.

"Perhaps 25% of this great difference in cost of the entire system is due to the fact that about 70% of the distribution mains have been wood-stave pipe instead of cast-iron pipe, the cost of wood-stave pipe being on the average about 60% of that of cast-iron pipe. The greater density of population in the camps has also contributed materially to reduce the cost of their water-works. But when every possible allow-

* *Engineering News-Record*, January 3d, 1918, p. 35.

ance has been made, the comparison of cost cannot be other than favorable to the camps.

"Finally, and infinitely more important, is the time comparison. The time allowed for planning and completing a water-works system for a city of 40 000 population would, under ordinary circumstances, be about three years; whereas with the most difficult material, labor and transportation conditions ever known in this country, the water-works for the 16 Army cantonments have been planned and completed in a little over three months."

From the nature of the case it has been impossible to secure any data, even approximately accurate, of the cost of later water-works systems built by the Construction Division. There can be no doubt of the fact, however, that the unprecedentedly bad weather conditions in the winter of 1917-18, the epidemic of influenza, and, above all, the constantly increasing cost of labor, coupled with its steadily diminishing efficiency, have all combined to increase the cost of work, not only on the projects carried out by the Construction Division, but on every project of whatever nature that has been undertaken in the United States.

In round numbers, about 4 000 000 troops and 2 000 000 civilians have been supplied with water by plants designed and built by the Construction Division. Up to date, this office has not been informed of any case of typhoid fever or other water-borne disease which has been attributed to any of these water supplies.

The barracks, mess halls and lavatories built by the Construction Division were necessarily of frame construction, and, therefore, very inflammable. Many thousands of fires have started, but in only three cases has a fire escaped beyond the building of origin. In each case the fire department at the camp succeeded in saving a part of the barrack building in which the fire originated and a part of the mess hall to which it spread. These fires were extinguished by the outside fire protection afforded by direct pressure from the water-works systems in the cantonment.

The records for 1918 show that the per capita loss by fire throughout the United States was $2.70, whereas the total per capita loss by fire at the Construction Division activities for the year ending June 30th, 1918, was only 67 cents.

The writer trusts that he has already made it clear that the work described in this paper was in no sense a one-man job. It would seem evident that results such as have just been set forth could not have been achieved without the loyal and intelligent co-operation of every one of the many men who bore a responsible part in the work, not only in the office, but in the field.

DISCUSSION

Mr. Fuller.

GEORGE W. FULLER,* M. AM. SOC. C. E.—Great credit is due to Col. Maury for the very efficient way in which he handled the water supply projects in the Army camps. It may seem, perhaps, at first sight, that the construction of water-works for these communities of some 40 000 people was a relatively simple matter, particularly when they are spoken of in a city like New York where such large water-works projects have been undertaken; but when one takes into account the fact that more than 30 camps, having an aggregate capacity of more than a million people, were supplied with water in a little more than 3 months, it is really a very remarkable record.

A part of the success of supplying water to these Army camps, carried out in the short time that it was, was due to the very level-headed consideration of these matters prevailing in the Washington office. That is to say, they did not try to do in Washington all that was to be done in the line of engineering. They got out only two or three pages of concise specifications as to fundamentals; they trusted the men in the field to adjust to local conditions; they were wise, in this respect, as well as in the local personnel selected and in the general oversight exercised to keep investments as small as practicable.

The speaker has seen a great many of the water-works enterprises of the Federal Government in the past two years, and knows that Col. Maury is entitled to much credit for the practical sense that he has exhibited at every turn.

Many of the engineers, at first, were inclined to try to introduce for the various branches of the military establishment schemes on the lines of metropolitan enterprises with which they were familiar, and which would provide more water than was actually needed; but Col. Maury was always at the helm, feeling his way along and heading off these large metropolitan water schemes that were not needed; and, at the same time, guarding against serious water shortage.

It is to be hoped that the methods which were established for handling these water supply projects will be recorded for the benefit of our military establishment for all time. Col. Maury also might have said quite a little about the operating steps taken to control the wastage, which was first sought to be effected by direct military order.

These details need not be recited here at great length; but, in addition to rigid inspection, many devices were introduced, such as putting marbles in the top of each header leading to showers and notching the end of the pipe on which the marble rests. The insertion of perforated metal blocks on top of headers was also used for reducing the quantity of water delivered to the large number of shower baths at the camps. There were about 15 000 fixtures in a single camp, and

* New York City.

Mr. Fuller.

wastage in some of them might have interfered seriously with the continuity of the supply. One other interesting procedure for restricting waste was the very simple one of bending down the float in each flush tank in the lavatories, so that there was a smaller discharge from the tank. The main fact is that they got along comfortably with 50 gal. of water per capita daily, as originally specified. This is a very creditable record, and reflects the benefit of the adequate engineering direction of Col. Maury and his associates.

Mr. Norcross.

P. H. NORCROSS,* M. AM. SOC. C. E.—The speaker, who has been working continuously for the past 22 months for the Construction Division of the Army, first as Supervising Engineer on Cantonments, and later as an Assistant to Col. Maury, had the opportunity, soon after the work began, of becoming intimately acquainted with what Col. Maury was doing, and the general specifications and instructions for supervising engineers, pertaining to water supplies at the Government enterprises; for these reasons he feels qualified to offer a few remarks.

At the beginning, few, if any, of the supervising engineers concurred in Col. Maury's suggestion, that an allowance of 55 gal. per capita daily was ample for all needs and demands, as they had gained their experience in American municipalities, and quite naturally felt that, not only was this quantity of water inadequate, but that such a suggestion was almost heretical. However, they accepted this figure, and constructed water supplies in accordance with the general specifications prepared by Col. Maury's office. The wisdom of the plan soon proved that 55 gal. per capita daily was sufficient for all the needs of the camps, and the early difference of opinion has been supplanted with almost unanimous approval by the consulting engineers and the Military Establishment.

Mr. Fuller has mentioned the importance of preventing the adoption of "metropolitan" ideas in the construction of camp utilities. Col. Maury realized this necessity at the beginning, and very quickly succeeded in impressing on the supervising engineers the fact that "time was the essence", and that costly refinements of design and construction would cause serious delays and were not essential to the building of cantonment water supplies.

One of the greatest economic municipal crimes of the United States is the extravagant use of water. In no city is this emphasized more acutely than in Washington, D. C., where the daily consumption runs as high as from 150 to 160 gal. per capita, and where practically 60% of the total water furnished is used by Government departments, for which no direct charge is made. The remaining 40%, which is used by the private consumer, bears the entire burden.

* Atlanta, Ga.

Mr. Norcross.

Much has been said regarding the speed with which the Construction Division supplied the War Department with camps. Speed was even more important in the construction of the water utilities, because of the vital necessity of establishing both temporary and permanent water supplies before the construction forces, and subsequently troops, could be quartered at the cantonments. To civilians, accustomed to the slow and systematic method in which cities and other bodies politic construct their utilities, the short time within which the water supplies were made available can only be accounted for as the result of a species of patriotic zeal and endeavor, unprecedented in history. This, in a large measure, was attributable to the cordial co-operation and enthusiasm that Col. Maury imparted to those who came in contact with him. The speaker and his fellow-workers could not help but be impressed with the necessity for urgent and more urgent action. To use a military expression, the *esprit de corps* of the Construction Division, composed practically of civilian engineers from all sections of the United States, is something that no one can explain, but it is a tangible memory that all can recall with pride.

Wherever it was possible, water was obtained from existing developed supplies, owned either by municipalities or private corporations. As a member of Col. Maury's staff, the speaker had the opportunity of negotiating, both with municipalities and public service companies, for the purchase of this commodity, and feels that some comments on the policy adopted by the Advisory Engineer for Water Supply in these negotiations may be of interest: Many of the National Army and National Guard camps were situated near municipalities, ranging in size from 20 000 to 60 000 people; consequently, if water was purchased from an existing supply, the demand on that plant was practically doubled. To the Advisory Engineer of Water Supply was delegated the powers of negotiating these contracts. To consummate these with fairness and equity to the seller, and, at the same time, to obtain reasonable rates and service for the Government, required, in addition to technical ability, unusual diplomacy and tact. The records of Col. Maury's office will show that there prevailed a closer harmony and co-operation on the part of the seller and buyer than has ever previously existed in public service dealings in America.

In many instances, due to increasing, or doubling, the personnel at the camps, the municipalities, or corporations, had to make a great increase in their normal facilities for supplying water. When these cases arose, the Government financed and constructed the work, and allowed the city, or private corporation, to reimburse on a basis of 75% of the actual cost to the Government, payments being made in water service, and interest charges on obligations thus incurred being deferred until after the cessation of hostilities.

Mr. Norcross.

In conclusion, the speaker desires to say that Col. Maury has reflected great credit on the American Society of Civil Engineers, the Construction Division of the Army, and the Engineering Profession in general, by his able and fair-minded method of seasoning his technical work with the proper modicum of common sense and fair dealing.

Mr. Goldsmith.

CLARENCE GOLDSMITH,* M. AM. SOC. C. E.—Because of the unfamiliarity of most of the Supervising Engineers with the laying of wood stave pipe, the work presented certain problems which had to be overcome with a minimum of delay. In those parts of the country where wood stave pipe had been used, it was customary to provide special bells, on valves, fittings, and adapters, which were tapered to receive the tenons of the particular pipe being laid. The diameters of the tenons of the several sizes of pipe of the several manufacturers were not uniform, and in most cases the individual manufacturers had a few patterns of the ordinary fittings with bells designed to fit the tenons of their pipe. In some cases the inner surface of the bell was only snagged and smoothed with a file; in a few cases the inside of the bell was machined. It is obvious that the machined bell made the better joint.

More than 1 100 miles of wood stave pipe were laid by the Construction Division, and, therefore, it was impossible to secure special castings and machine them in order to provide for the bends, branches, and adapters required.

Owing to lack of experience, together with the haste with which the work had to be done, and the resultant makeshift methods used in many instances, it was feared that the underground leakage would be excessive. This, however, did not prove to be the case, for as soon as the Maintenance and Repair Division got the operation of the water systems under control, tests showed that the average leakage in the 20 or more miles of mains in each of the several camps was not more than 200 000 gal. per 24 hours, and, in one camp, it was found to be about 100 000 gal. This rate does not compare unfavorably with that ordinarily found in distribution systems laid with cast-iron pipe.

In order to assure the tightness of the system, it is absolutely necessary to leave the trench open, with only a small quantity of filling replaced over the pipe between the collars, to prevent the line from floating, in case the trench becomes filled with water, and to keep the pipe line filled with water under little or no pressure for several days, in order to allow the staves to swell. When the line is ready to be tested, a pressure of about 50 ft. in excess of the working pressure should be applied, and all leaks which are found should be stopped by inserting plugs or wedges. It is desirable to have at least one man

* Chicago, Ill.

who is experienced in laying wood pipe, in order to direct the work and repair any leaks. Mr. Goldsmith.

In some cases considerable objection was raised to keeping the trenches open long enough to permit the test, but the necessity of making it more than counterbalanced the inconvenience involved. If leaks are not stopped before back-filling, the escaping jet of water frequently forms a sand-whirl which quickly cuts the wire and causes the complete failure of a section of pipe. In one case a sand-whirl cut completely through a 1-in. corporation cock.

Service connections to fir pipe (which has a thick stave) were made by inserting a corporation cock with a wood thread into a hole of slightly smaller diameter which had been bored with a bit. The thickness of the shell of the redwood pipe is insufficient to assure the holding power in all cases, and it is desirable to have saddles, with outlets of the desired sizes, wound on the pipe to receive the corporation cocks. The standards developed for service pipes provide for screwing the iron pipe directly to the corporation cock. It was not considered necessary to provide lead goosenecks, and experience has shown that they were not necessary. The saving of material and labor thus effected was considerable.

The speaker is of the opinion that, even if it had not been necessary to conserve cast iron and steel, the use of machine-wound wood stave was justified, both because of its lower cost and because it could be laid so quickly. Although machine-wound wood stave pipe cannot be considered as desirable beneath permanent pavement, in closely built-up sections, it is certain that it is adapted for use in a much larger field than has previously existed, particularly for force mains and in undeveloped sections.

T. Kennard Thomson,* M. Am. Soc. C. E.—The Society is much indebted to Col. Maury for this very valuable paper. The work done by the Army and Navy engineers has wakened the whole profession, and cannot fail to have a broadening effect on future engineers as well as on those of the present time. Mr. Thomson.

The reference to placing the water and sewer pipes where they will always be exposed to view, makes the speaker hope that this practice will become much more general than it is at present. He remembers the time when it was impossible to reach the plumbing, in most cases, without doing great damage to the house, and, even now, it is impossible to reach water, gas, sewer, or other pipes without tearing up the street—an almost continuous operation. The sum paid for such work would be more than enough to pay for putting all such pipes in permanent tunnels, so that the streets would never have to be torn up, except to repair the roadway.

* New York City.

Mr. Thomson.

A few years ago a water main broke, over a subway that was being built, and started to flood an adjoining cellar. It took three hours to get the city to turn off the water, and the only way a catastrophe was avoided was by constructing a dam of sand bags and diverting the water into the sewers.

Quite recently, when some caissons were being constructed on lower Broadway, New York City, the water level rose 9 ft. above normal, just as the compressed air was put on the work. At first, the Water Department thought that the work had caused the water to rise, which, of course, could not be. The work was continued, and the water level dropped back almost 11 ft. Some of the new subways are below the water level, and may or may not be affecting it, but it seems to be certain that the water level in lower New York City cannot rise and fall from 9 to 11 ft. under old buildings, which rest on the so-called New York quicksand, without sooner or later wrecking some of these buildings. It might be stated here that the ground-water in lower New York City used to stand always from 6 to 9 ft. above the high-tide level.

The object of these remarks is to lead up to the hope that, in the future, proper tunnels will be constructed for all pipes and wires, and that even the subways for cars will not be holes in the ground, but constructed so that there will be sidewalks and stores throughout their whole length, on both sides, and an opening, 2 or 3 ft. wide, in the center of the street, for the whole length of each block, so that the subways will always be attractive and well-ventilated, thereby greatly enhancing the value of the adjoining property and the health of the community.

Mr. Mason.

W. P. Mason,* M. Am. Soc. C. E.—The speaker is particularly interested in Col. Maury's reference to the use of chlorine, as he is a great believer in some form of emergency defense, so that, in the event of sudden need, the people can be protected against a threatened catastrophe.

He is also greatly interested in what was said in reference to the daily quantity of water supplied, and is impressed by the wisdom shown by the author in deciding that 50 gal. per capita would be sufficient. In every community there are many who insist that water should be "as free as air", and many believe that large quantities are needed to flush the sewers. If they would only call to mind the little dribble that runs along the bottom of a large sewer, except in the case of a heavy rainfall, they would realize how small is the chance for sewer flushing under normal circumstances.

There is no reason for taxing a man for his neighbor's use or misuse of water, any more than there is for taxing him for his neigh-

* Troy, N. Y.

bor's consumption of gas; but, in the northern part of New York State, it seems to be absolutely impossible, so far as the speaker can find out, to keep the people satisfied with 100 gal. per capita per day. Perhaps they will feel differently after July 1st. The speaker does not know what the future will bring forth, in the matter of educating the public, but, to his mind, 100 gal. per day is enough for the average mortal. Mr. Mason.

J. WALDO SMITH,* M. AM. SOC. C. E.—The speaker, unfortunately, has not been very close to any of this great work which Col. Maury has been doing; but from what he knows about it, it seems that the War Department was singularly fortunate in securing the few men gathered together in Washington, men of very broad experience and excellent judgment, who laid down the skeleton of the foundation for this work. Mr. Smith.

Secondly, the Department was fortunate in the personnel which was developed to carry out this work, and afterward to take charge of its maintenance and operation. This was done at great personal sacrifice on the part of a great many of these men, in many instances, as the speaker knows; and it is perfectly true, as both Col. Maury and Mr. Fuller have stated, that, following general directions, they were left largely to their own devices to develop those plants and expedite the work.

Col. Maury mentioned the form of contract under which this work was carried out. The speaker agrees with him that that was the only form of contract to be adopted under the circumstances; but he does not agree with the statement, in an address† by Gen. Marshall at the Annual Meeting, in January, in which he advocated the continuance of this form in general contract work after the war, because, in the speaker's opinion, the general adoption of such a form in ordinary work would be absolutely demoralizing to the whole contracting fraternity and very much against their interest, and, eventually, would lead to favoritism and discrimination, as well as the elimination of the gambling element, which is one of the principal interests in contracting.

Besides, there would be no chance for the man of great inventive resources, who is full of expedients and develops new methods of doing work.

To the speaker's mind it would result in a great deterioration of the contracting organizations. He does not know Col. Maury's opinion on this subject, but he was very much surprised to hear Gen. Marshall put it forth as a desirable feature. Certainly, the work of this Construction Division, of which so much has been heard during the last month or two, seems to appear as the bright and shining light of all the activities of the Army. This work seems to have been excellently planned and carried out, even to the details of operation and maintenance.

* New York City.

† *Proceedings*, Am. Soc. C. E., February, 1919, pp. 164–171.

Mr. Smith. Of course, difficulties were encountered, but it seems that most of them were anticipated and prepared for beforehand; and when they were encountered, very prompt and effective methods were taken to remedy them.

Mr. Thurston. E. T. THURSTON,* M. AM. SOC. C. E.—The speaker's experience with the water problem in military camps was as a consumer only. At Camp Devens, Mass., where his unit was mobilized, during the bitter cold winter of 1917-18, water was abundant, and every desirable facility was afforded for its application to the needs of the men, thanks to the energy and foresight described in Col. Maury's paper. In France, however, the situation was quite different. Not only was there a scarcity of water, but the systems were primitive, following French practice Strict economy was the watchword everywhere, although in less degree at the headquarters camps than elsewhere. In the wash-houses, water was delivered into overhead wooden troughs, about 8 by 6 in. in size, fitted with small wooden spigots at intervals of 2 ft. or so, which would emit a very small stream of water into the waiting hands of the washer. Wash-basins were not used, and usually guards were present to prevent the waste of water. Drinking water was chlorinated in canvas bags from which it was drawn as required; the drinking of unchlorinated water was prohibited.

Shower-bath houses, with water heaters, were provided, but in many cases were of little or no use on account of the water shortage. This was the case at all the camps at St. Nazaire, except the headquarters camp. On arriving with his company, the speaker was informed by the Adjutant that the bath-houses were not to be used on account of the shortage of water. Thus, thrown on our own devices, we overcame the difficulty and incidentally provided the necessary hot water for cleansing mess kits, by foraging some pipe and a barrel, constructing a water coil for the field stove, and carrying hot water in buckets to supply the wash-house tank. The men were withheld from their details in convenient detachments, so that each man had a warm bath once a week. This case serves as a fair illustration of the ingenuity and energy displayed by American troops in overcoming incidental obstacles that confronted them.

The record of achievement provided by Col. Maury's paper is noteworthy. There are many others in every branch of the Service lacking publicity, and, it is hoped that a comprehensive record of the achievements of reserve officers in connection with the war will be prepared by sympathetic and informed persons.

Mr. Boorman. K. M. BOORMAN,† ASSOC. M. AM. SOC. C. E.—The speaker, whose last duty overseas was with the Water Service of the Second Army,

* San Francisco, Cal.

† New York City.

Mr. Boorman.

feels that Capt. Thurston has given an inadequate idea of the water supply work in France. The Water Supply Service of the American Expeditionary Force was under the charge of Col. F. F. Longley, M. Am. Soc. C. E., who, the speaker believes, is known in New York City as a water supply engineer of some prominence. This service grew up with the development of the A. E. F.

During the first year, the water systems were usually built by the construction units locally engaged in building the camps and bases, as well as the general construction work for the camps. Of necessity, the supply varied with the size and importance of the camp, and those built entirely by the American army acquired better systems than those enlarged from old French camps using inadequate French systems as a basis. At the large aviation center at Romorantin, a field built on a new site by the Construction Division of the Air Service, water was supplied, a few months after the work was started, to all the buildings for drinking purposes and shower baths, through a modern system of piping from the Sauldre River.

On August 8th, 1918, the Water Supply Service was ordered to be organized, to be composed of "certain officers and certain engineer troops", to be a separate organization under the direction of the Chief Engineer of the A. E. F. By October, when both the First and Second Armies, fully organized, were operating on their own fronts, the Water Service was working thoroughly and efficiently. The 26th Engineers, with units of Pioneer Infantry attached to do the common labor, were assigned for this work in the Army areas.

"Water points" were established at all practical places. A typical procedure was to pump water from streams (such as the Rupt de Mad River in the Toul Sector) to a concrete settling basin, and run it through sand filters to a clear-water basin from which it was pumped into the pipe lines. It was usually necessary to chlorinate the water at the filters. From these basins the water was pumped to storage reservoirs accessible to the water tank trains of wagons and motor trucks, which were also part of the Water Service.

In many cases water was pumped through 4 and 2-in. pipe lines directly to the batteries firing on the German lines. During the last month of the war, the detachment of Co. B, 26th Engineers, near Thiaucourt, in front of Metz, connected their own pipes to miles of German pipe lines laid in the area gained in the St. Mihiel drive. This German piping was of sheet-iron and spiral-wound, usually about 3 in. in diameter; the American was the usual screw-fitting iron pipe. The pipes were buried to a depth of 1 m., for protection against frost and shrapnel.

The speaker hopes that, on the return of Col. Longley and Maj. A. H. Pratt, M. Am. Soc. C. E., Chief Water Supply Officer of the

Mr. Boorman. Second Army, they can be induced to present a paper on the work of the Water Service in France, of which the instances cited are only a small part.

Mr. Boucher. WILLIAM J. BOUCHER,* ASSOC. M. AM. SOC. C. E.—The Charleston Port Terminal, at Charleston, S. C., on the Cooper River, about 11 miles from the City Hall, is an exceedingly well planned rail and water terminal, consisting of an Animal Embarkation Depot, an Ordnance Depot, and a Quartermaster Depot. The property, Fig. 14, is traversed by the main line of the Seaboard Air Line Railway, is contiguous to the main line of the Atlantic Coast Line Railroad, and is also served (through connection) by the Southern Railway.

The Cooper River is a broad stream with considerable current, and, by a moderate amount of dredging, a channel depth of 30 ft. has been obtained. The ground is generally level, its elevation varying from 5 to 25 ft. above sea level; the surface is sandy, and the drainage is very good. When acquired, the land was partly covered with pine forest and partly devoted to agriculture.

The Animal Embarkation Depot or Remount (Mule) Station is at the westerly end of the reservation, and has accommodation for several thousand mules or horses. The pens or corrals are composed of simple fences, about 5 ft. high, without roofs. Hay is fed to the animals from a rack in the interior. The corrals are of varying sizes, according to the uses for which they are intended, and are joined by lanes with suitable gates. There are, in addition, the necessary office buildings, barracks for the troops caring for the animals, blacksmith shop, warehouses, feed buildings, and (open) hay sheds. Manure is shipped away in cars.

The Ordnance Depot covers an area of approximately 1 sq. mile, and is bounded on all sides by standard-gauge tracks, which, in turn, are connected by several parallel tracks. On each of the tracks, *D*, *E*, *F*, and *G*, there are eleven smokeless powder magazines, or forty-four in all. These are 32 by 96 ft., of wood-frame construction, covered with corrugated asbestos siding and a roof composed of gypsum blocks, covered with prepared roofing, rendering them fire-proof from the outside. The several buildings are separated from each other approximately 400 ft., in all directions. On tracks, *I*, *J*, *K*, and *L*, there are twenty-seven standard magazines, each 50 by 220 ft. These have brick pilasters supporting the wood roof-trusses, hollow-tile walls, and gypsum roofs (built in place, similar to reinforced concrete). On Track *O* there are eight primer and fuse houses, each being 32 by 96 ft. These have hollow-tile walls, wood rafters, and gypsum block roofs. There are seventy-nine buildings, of these three types, for the storage of explosives. There are, in addition, several guard-houses for the

* New York City.

Mr. Boucher.

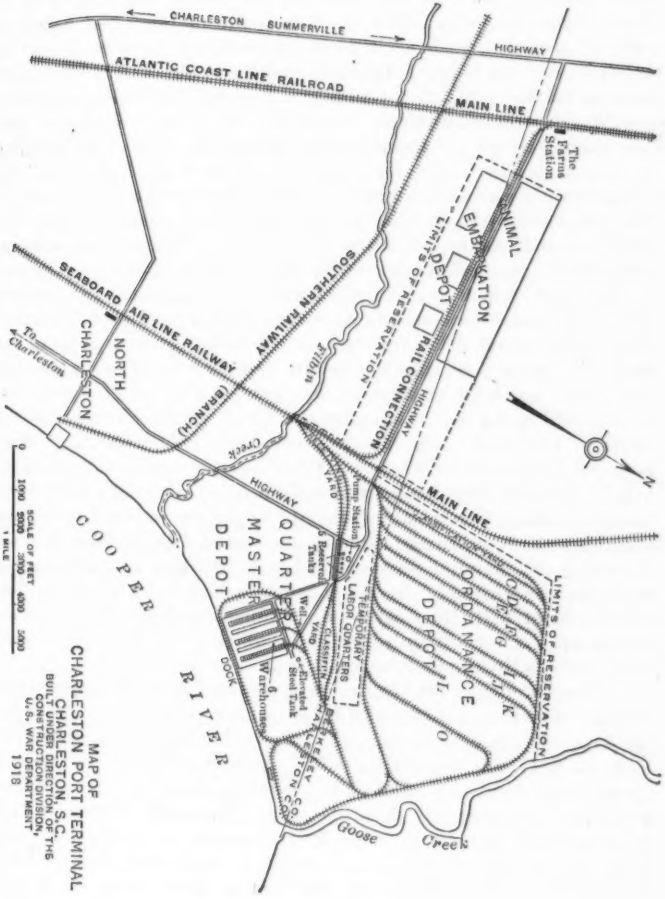

FIG. 14.

Mr. Boucher.

use of troops patrolling the area, a garage and battery-charging station, and a commodious administration building.

For the use of the Quartermaster Department there were planned six warehouses, each 160 ft. wide and 1 200 ft. long, and two open sheds of the same size, but work on the latter was stopped at the time of the Armistice. The warehouses are of brick and hollow-tile wall construction, with wood posts supporting a wood roof, and are only one story in height. They are divided by fire-walls 100 ft. apart, making twelve rooms to a building. A complete sprinkler system is provided for these buildings. On each side of each warehouse there are railroad tracks and team or motor driveways. One of the buildings is two stories in height for about one-third of its length, and this second floor is used as the Administration Office for the officer in charge. The warehouses are parallel to each other and normal to the dock, which extends along the shore of the river; all the warehouses are joined by a long head-house, which, in turn, gives directly on the dock.

The dock, which is a marginal wharf, extends from the southerly side of the first warehouse, in a northeasterly direction (following the river bank) about 3 300 ft. It was originally planned to be of concrete piles with a reinforced concrete deck, but the plans were modified, and it has been constructed of creosoted piles with a timber deck. A standard gauge track, running the entire length of the dock, connects at both ends with the tracks on shore. For handling freight between warehouses or to ships, storage-battery trucks have been provided. Each carries about a ton, and, in turn, can haul several loaded trailers. Along the front of the dock, for its entire length, wood sheathing has been driven, forming a bulkhead, behind which has been deposited the material pumped up by the dredges in deepening and widening the channel. In this manner a large area of marsh land, overflowed at high tide, has been reclaimed, and the fill serves as a protection for certain untreated piles which were driven, the teredo being very active in the Cooper River.

The water supply for Charleston is obtained from the upper reaches of Goose Creek, and impounded by a dam approximately 20 miles from the city. Because of the greatly increased demands for water since early in 1917, and on account of the very dry summer of 1918, the supply proved entirely inadequate for the needs of the Terminal, and plans for increasing it were made early. Two wells were sunk in the Remount area and one near the Quartermaster warehouses; these are from 441 to 535 ft. deep, and supply a very good water, slightly impregnated with sulphur. In addition to these wells, an arrangement was entered into with the City of Charleston for increasing its supply, with Government aid. A dam has been constructed across the head-waters of the Ashley River and a 24-in. conduit of wood staves has been laid along the Charleston-Summerville Highway, connecting

with the supply pipes leading into the Terminal. The reservoir for the Terminal consists of five circular wood tanks, on concrete foundations, each having a capacity of 200 000 gal. These tanks are near the pumping station, and the water is distributed from the latter through cast-iron pipes varying from 16 to 6 in. in diameter, for drinking, sanitary, and fire purposes. Some 12-in. wood-stave pipe is used between the 24-in. main in the highway and the reservoir. There are eighty-nine hydrants distributed about the grounds. A 10-in. pipe runs along the entire length of the dock, the head-house has a 10-in. wrought-iron main, and the warehouses are protected by sprinklers, the supply for the latter being contained in a 200 000-gal. elevated steel tank near-by. Mr. Boucher.

During construction, temporary mains, up to and including 3 in. in diameter, were laid through the Ordnance area for mixing concrete, and 1 and 2-in. pipes supplied water to the inhabitants of the temporary camp. All these pipes have been removed. Permanent barracks for the use of stevedores (troops or civilians) have been erected, and in separate buildings there are lavatories and toilet facilities, similar to those at the several cantonments. There has also been constructed a power-house and refrigerating plant, and a commodious fire-engine house, containing a new model, chemical, motor-driven engine.

The Terminal was constructed jointly by The Degnon Contracting Company and The Mason and Hanger Contracting Company, on a cost-plus-fee basis, under the direction of the Construction Division of the War Department.

MORRIS KNOWLES,* M. AM. SOC. C. E.—The speaker has had the opportunity of reading a report by M. R. Scharff, Assoc. M. Am. Soc. C. E., on the water supply in the region of Brest, and is impressed with the accuracy of the statement relative to the materials and other facilities for water supply protection in France being far less adequate and complete than were those for similar work done in the United States. It must have been true that much of this work was carried on with insufficient quantities of absolutely essential materials. Mr. Knowles

The speaker cannot refrain from adding a word of commendation for the work of Col. Maury and his associates, or from expressing his gratification at having had the opportunity to serve in the Cantonment Construction Division water supply work under the direction of Col. Maury; and in commending this work, he wishes to speak especially of the independence and foresight with which Col. Maury and his staff assumed the responsibility of fixing the limit of use of water to be allowed in design. All know how difficult it is, in municipal water supply work, to convince people that a limited quantity of water constitutes a reasonable supply, and to combat the old fallacy that water

* Pittsburgh, Pa.

Mr. Knowles.

should be as free as air. There is no doubt that many felt, at the time of this decision, as the speaker did himself, that there was serious doubt whether a limitation of designs and installations to a basis of 50 or 55 gal. per capita per day could be successfully applied. It is clear that the success which justified this decision was due, in a large measure, to the restrictive measures inaugurated for preventing excessive use and for distributing the peak loads by planning hours of use for various purposes. It would be interesting if Col. Maury would enlarge on these restrictions in his paper, and on the difficulties encountered in enforcing them because of conflicting military orders by the commanding officers of troops. In the speaker's experience, considerable difficulty was encountered from this source, and, as a result, a shortage of water occurred during certain hours of the day for a large part of the time.

The method of supervising the work of which Mr. Fuller spoke was certainly admirable, in that it offered many helpful services while leaving to those at the different camps a large measure of discretion and responsibility. It was not always altogether easy, however, to confine this supervision within the limits of this conception. If time had been available to discuss every question, close supervision and detailed review would undoubtedly have resulted in more perfect and generally satisfactory designs. Under the circumstances, however, when everything had to be done in haste, it was inevitable that such close supervision and detailed review should have been, in some cases, impossible, and, in other cases, the cause, either of delay, or of resultant designs, suggesting the presence of two different and incompletely harmonized conceptions of the situation.

One of the most troublesome problems in connection with cantonment water supply was the provision of a temporary supply. In the beginning there was a tendency to commence work at different points, without consideration of the difficulty or impossibility of supplying water at these points from any reasonably near source. Similar difficulties were encountered with the construction camps, which grew very rapidly, and with the National Guard units which arrived on the ground early for the purpose of establishing guards and protecting property. Frequently, these latter units were commanded by officers of limited military experience who would wish to select camp sites which were not well adapted for the supply of water and the disposal of wastes. One of the things that kept the supervising engineer busiest at the beginning of the work was the location of such units so as to utilize in the best way the natural resources, and especially the shallow underground water resources, of the site. In spite of every effort, it was often impossible to avoid supplying such camps by transporting water in carts.

Mr. Knowles.

Referring to Mr. Smith's remarks about contracts, the speaker is in agreement with all those with whom he has been associated on war-time construction work in believing that the form of contract used was the only one that could have been successful under the circumstances. In the same way, it was necessary to have similar contracts for the housing developments which were constructed by various governmental agencies for the emergency. It does not follow, however, that such contracts are desirable for work of this character carried out under more nearly normal conditions—although the speaker believes that it is possible to draft contracts based on cost-plus-a-sliding-scale fee, which may be advantageous at all times. The Emergency Fleet Corporation, with which the speaker has recently been associated, is canceling many of its housing development contracts on the cost-plus basis and letting the work anew on the unit-price basis. Not only has this been the means of saving a great deal on overhead charges, but it is gratifying to know that much lower prices are being secured on the unit-price basis than if the work had been continued on the cost-plus basis.

In conclusion, the speaker desires to express his gratification at having had the opportunity of being connected with the cantonment work—a feeling which he is sure will grow as time goes on and as the troubles connected with the work are replaced in his memory by the more pressing ones of other work.

Mr. Dunham.

H. F. DUNHAM,* M. AM. SOC. C. E. (by letter).—An important item in this interesting paper is the allowance of 50 gal. per capita. Every superintendent and manager of water-works has estimated the reduction in waste if he could have his consumers placed under military discipline. All have some knowledge of the subject. Figures from the average city are misleading, because they are obtained by using the population as a factor, whereas many people may obtain supplies from deep wells or other sources. A correction would increase the per capita allowance, but the cantonment figures are definite. Although a few cities like Fall River, Mass., and Providence, R. I., could have been cited as object lessons, courage was necessary in order to estimate as low as 50 gal.

The reply to one question—which may not be a fair one—would be of great interest: With the experience thus far gained, would the author, on a similar demand for advice to the Government, recommend the same per capita allowance?

It would also be interesting to know to what extent the force-main capacities were determined by fire-protection needs, and whether extra high pressure at the pumps was used in order to provide for the domestic supply during such a short period as a fire might continue.

* New York City.

Mr. Johnson.

GEORGE A. JOHNSON,* M. AM. SOC. C. E. (by letter).—The highly important functions performed by Col. Maury in connection with the great work of the Construction Division of the Army, makes noteworthy his becoming modesty in describing his participation in the unparalleled achievements of the Division and the happy manner in which he shares his very creditable record with his associates. It appears to be pretty well recognized at this time that the Construction Division as a whole accomplished a feat unequalled in the building history of the world, and, in this performance, Col. Maury is clearly correct in the premise that there is ample credit and glory for all who had a hand in it.

The rank and file of the Division, in addition to the material work they accomplished, established still another record of quite a different, and perhaps of quite as noteworthy, a character. As paper advertisers of their Division they made a sorry record, and as seekers after the plaudits of the public, they were almost a total loss. Probably no such aggregation of "go-getters" and "do-it-nows" was ever before brought together, and the conspicuous absence of endeavors to secure personal benefit from the work they were doing in the great emergency redounds to the credit of the organization as substantially proving that they were laboring unselfishly to serve their country first, last, and all the time.

On reading Col. Maury's paper one may at first thought conclude that with such utterly unprecedented methods of providing water supply facilities in the camps and cantonments as were of necessity followed in 1917, inadequacies, inapplicable features of importance, and structural inferiorities would make the road of the operating man who came after the intensive builder, a rocky one indeed. The writer was that man, and when he, like Col. Maury, was wired into the service (not by the time-consuming telegraphic process applied in Col. Maury's case, but by the quick acting telephone), he contemplatively reviewed on the train the probable formidable array of difficulties to be overcome because of the very nature of the problem, and the obstacles to success which he might reasonably expect to encounter, due solely to the speed with which the various systems had been put together.

Before he was made Assistant to Col. C. D. Hartman, Officer in Charge of the Maintenance and Repair Division, the writer was in direct charge of the Water and Sewage Section thereof, and, as such, exercised supervisory control over the water supplies in about 400 military establishments. In the permanent establishments the population to be served increased materially, following the declaration of war, of course, and, in each case, provision for adequate and pure water supplies had to be made, in order to keep step with the requirements, and a little ahead of them. In the camps and cantonments,

* New York City.

Mr. Johnson.

although the problem was one involving entirely new construction, two factors introducing important complications had to be faced and solved satisfactorily, namely, to get the systems functioning on time and to provide, so far as was humanly possible, for the fluctuating population.

It is remarkable at this date to review the events following September, 1917, when the first increments of the new army began to arrive at the camps. The water systems were made ready in time; the supply was sufficient and pure; and fire protection well cared for by ample water pressures. All the water systems had been designed on a basis of a certain fixed estimated number of troops and animals at each individual camp, and a factor of safety of 2.85 times the average demand allowed in order that peak load consumptions might be anticipated satisfactorily.

The rapidly fluctuating camp population was perhaps the most difficult problem for the operator to meet, and a matter which the designers of the water systems could not anticipate with precision. A notable case in this line was Camp Dix which was laid out in all its parts for a maximum population of less than 45 000. At 3 P. M., on one day, the population was 44 000. At 10.00 A. M., the day following, it was 60 000. The population of a small city had been moved in over night. How many city water superintendents have ever had such a problem to meet? With the facilities provided by the designers and the exercise of considerable resourcefulness on the part of the Utilities Officer, however, every man was adequately supplied with water, and fire protection requirements were met.

The water systems at all the military establishments were equal to the demands made on them. Naturally, in some cases, additional storage had to be provided, more pumping capacity, and similar augmentations made in the original systems, but the outstanding fact is that, as a whole, these water systems, conceived over night as it were (a fact confirmed by Col. Maury's description of the work at Camp Lewis), built in a mere fraction of the time usually required for such work, and called on to function satisfactorily from the start, did what they were expected to do. It was little short of a miracle that they did.

At the close of 1918, the Maintenance and Repair Division of the Construction Division of the Army had charge of the operation and maintenance of the water supply, sewerage, electrical, heating, refrigeration, and fire-fighting plants and systems, and the maintenance of the buildings and roads, in 46 camps and cantonments, 51 hospitals, 66 border stations, 25 supply depots and terminals, and 271 regular military posts, and, for its uses during the fiscal year ending June 30th, 1919, funds to the amount of $62 400 000 were allotted. Its field force, concerned solely in such operation and maintenance work at these points, numbered 452 commissioned officers and 16 559 enlisted men.

Mr. Johnson. In the head office in Washington, there were 20 commissioned officers and 126 civilians at the close of 1918.

At each completed project, in charge of the operating force, there is an officer selected on his record in civil life in the management of public utilities, holding a position comparable to that of city manager, but with detailed responsibilities and duties far transcending those of such an official. Indeed, he is a composite of city manager, city engineer, fire marshal, street and building inspector, manager of municipal water-works and sewers, telephone and electric supply companies, and cold storage, besides being general all-around handy-man to whom everybody comes to get anything fixed.

The local field organization is military in its character, and was worked out with a view to obtaining the greatest efficiency and the best results with a minimum of personnel and expense. A major is usually placed in charge of this highly important work, and has as assistants a number of commissioned officers of lower rank. For operative and clerical assistants, there is a detachment of enlisted men, the number depending on the size of the project, but varying from 300 to 800 in various camps and cantonments.

Each utilities officer maintains in his office a "trouble department" —a desk over which passes every complaint of whatever nature and every request for repairs and replacements. In addition to the written communications received, the number of telephone calls in the trouble department at each camp averages several hundred per day. All the work is supervised, co-ordinated, and administered from the Washington office. Refinements and economies are constantly worked out, and their effect is always toward giving the greatest service with a minimum expenditure of public funds. The Maintenance and Repair Division of the Construction Division's office is really a huge service organization, operating for the benefit of more than a million persons in several hundred locations, and designated to supply them with every convenience and comfort incident to their existence as soldiers.

Failure in the great task delegated to the Construction Division of the Army was freely predicted, but the seemingly impossible was done effectually and economically. No greater tribute can be paid to those whose ability, untiring energy, and unselfish devotion were directly responsible for the successful performance of the colossal task of building the camps and cantonments in which to train the new army, and the other facilities required to make ready its translation to French soil, than to say that they were not found wanting in the supreme undertaking to which the nation had dedicated itself. Not only this, they have managed uniformly the hundreds of military establishments built by them in a fashion calculated to inspire improvement in existing methods of doing work along more or less parallel lines in civil life.

F. R. HARRIS,* M. AM. SOC. C. E. (by letter).—Although this paper necessarily is of such a brief and general character that what the writer is about to state can hardly be considered in the nature of a discussion of its technical details, nevertheless, he would like to add his praise to the high character of the work performed by the Construction Division of the Army, and especially to the very excellent results produced by Col. Maury, as Advisory Engineer in general charge of the water supply development in connection with the cantonments and other kindred work. It was certainly of the greatest benefit to the country that the services of such able experts as the author and others whom he has mentioned as having assisted him, were made available to the Government. Mr. Harris.

During the early part of the war, the strenuous efforts of the United States to expedite its military programme resulted in the concentration of work in various locations along the Atlantic seaboard. In some places this concentration resulted in congestion and overcrowding so that in the smaller communities what are known as public utilities were thoroughly incapable of meeting the demands of the military and civil population congregating around these centers. This was especially so in and around the Port of Norfolk (using the word "Norfolk" as a designation to embrace the Port of Hampton Roads). The Port of New York was being used to its greatest capacity. It was so greatly developed and had been built up so normally that it was not susceptible of great expansion. The port facilities which Hampton Roads offered, were naturally great, but undeveloped.

On the Newport News side, the War Department had undertaken the construction of general embarkation camps, animal embarkation camps, corrals, storehouses, hospitals, and various other necessary works. On the Norfolk side, it started a huge new Army Supply Base, took over the terminals of the Norfolk and Western Railway, and proceeded to develop and enlarge these for an Engineers' Material Embarkation Depot. At Pig Point, near the mouth of the Nansemond River, it planned a large Ordnance Embarkation Station; later, at Camp Abram Eustis, on the Newport News side, it constructed one of the largest of the artillery encampments and proving grounds.

The Navy Department had well under way the plans for enlarging and rebuilding the Norfolk Navy Yard, the construction at Sewall's Point, on Hampton Roads, of a Naval Operating Base, a great extension of the Naval Magazine, and, later, the construction, in the vicinity of Yorktown, of a Fleet Fuel Oil Reserve Depot and Ordnance Station. Directly to the north of this, the War Department, under contract with the du Ponts, planned a huge shell-loading plant at Penniman. The Navy Department and Shipping Board jointly under-

* Rear-Admiral, C. E. C., U. S. N., Norfolk, Va.

Mr. Harris.

took great extensions in the Newport News Shipbuilding Plant, and, incidentally, the various Departments interested took over for operation in connection with the Railroad Administration the large coaling plants of the Chesapeake and Ohio, Norfolk and Western, and Virginian Railroads.

All these construction activities starting at or about the same time, and entailing together a cost of approximately $200 000 000 taxed this community far beyond its capacity to furnish the requisite labor, house the labor furnished, and, considering the military personnel on the Newport News side, amounting usually to about 50 000, and the naval personnel on the Norfolk side, amounting probably to 20 000 men, resulted in practically a complete breakdown of all community utilities such as transportation, electric power and light, roads, water supply, etc.

In the earliest days of this problem, Col. Maury, acting for the Construction Division of the Army, attempted the task of expanding and extending the water supply in the vicinity of the Port of Embarkation at Newport News, and began to study the problem of the Norfolk water supply. Practically, single-handed, he obtained much information for future use and did much good on the Newport News side within the limited funds and authority at his disposal.

The conditions of congestion previously enumerated resulted in the inevitable. None of the work on the programme could be pushed, there were insufficient men, materials, and resources, to push all of them at once, and as there was no priority as to which should be done first and no organization to plan for systematizing the work, orders for which had been issued by several different Departments and Bureaus acting independently of one another, congestion, waste, and a most serious labor turn-over resulted. The two military Departments, War and Navy, finally attempted to correct the difficulties by appointing a representative of each Department to confer and agree on priorities, etc. Later, this was expanded into what was known as the Board of Control, War Construction Activities, in which the War and Navy Departments, the Department of Labor, U. S. Housing Corporation, U. S. Employment Service, Railroad Administration, Fuel Administration, Shipping Board, Emergency Fleet Corporation, and, later, the War Industries Board, were represented, of which Board the writer became President. The agreement as to the organization of this Board and its scope and authority was subscribed to by the Secretaries or heads of these various Departments, and an attempt was made through it to co-ordinate the efforts in the Hampton Roads District for the general good, with the idea of advancing the war construction programme. This Board soon gave its attention to the conditions of congestion and to the inadequacy of the utilities serving the port. Funds were secured through the instrumentality of

the Chief Executive from the various Government Departments interested, and allotted to the performance and securing of adequate water supply, transportation, light and power, roads, etc. The writer then first became acquainted with Col. Maury, and was guided and advised by him relative to the needs for water supply extension in the District. Col. Maury also played a large part in the plans and programme finally decided on and approved for securing potable water to meet the demands of the Port of Norfolk. Mr. Harris.

In this preliminary work, it is only fair to state that the services of Maj. J. A. Bensel, Corps of Engineers, U. S. A., Past-President, Am. Soc. C. E., who had been assigned to the Board as an assistant, contributed largely and, in fact, first brought to the Board's attention the conditions with respect to the water supply and the absolute need of taking immediate steps to secure its extension and enlargement, as an alternative to seriously hampering the War Department's plans with respect to the use of the port for the embarkation of the assigned quota of military forces to be transported to France.

Col. Maury impressed the writer at the conference at Washington so favorably with his thorough knowledge of local conditions, and his familiarity with what was needed, that, in the allocation of the improvement in water supply of the port, the writer advocated that this work be entrusted to the Construction Division of the Army, with the understanding that Col. Maury was to give it his general supervision. Under that arrangement Col. Maury took up the negotiations and planned the work for the extension of the Newport News water supply, thus practically trebling its original capacity, the extension of the Portsmouth water supply on about the same basis, and a co-ordination of the two separate water supplies of the City of Norfolk, with a view to placing them under one management. All this work, which is now completed, or rapidly nearing completion, although not carried out to its fullest extent on account of the end of the war, has involved an expenditure of upward of $5 000 000. Considering the limited time and the various other difficulties which the writer has not time to enumerate, but which are common to war construction activities undertaken in times of such great stress, the work has been well carried out to the great credit of Col. Maury and the organization which he represented.

The writer desires principally to state, as a matter of record, his appreciation of Col. Maury's zeal, untiring effort, and willingness, under the most adverse conditions, to carry out the very great public service that he performed.

MAURICE R. SCHARFF,* M. AM. SOC. C. E. (by letter).—As one who worked, as far as water supply was concerned, under the supervision of Col. Maury in the stirring days of July to October, 1917, Mr. Scharff.

* Pittsburgh, Pa.

Mr. Scharff.

the writer desires to express his appreciation of having had the opportunity to take part in the fine work of the Cantonment Construction Division, and the pleasure with which he will always remember the helpful attitude of the Washington office. Perhaps its greatest helpfulness lay in the fact that the plan of operation, as described in the paper, was not always strictly enforced and that a large measure of freedom was left to the Supervising Engineers in planning and constructing the work, while the supervision of the Washington office was confined to the enforcement of general standards and to help in securing rapid deliveries of materials.

The conditions under which the writer served as Deputy in Charge for Morris Knowles Incorporated, Supervising Engineers at Camp McClellan, Anniston, Ala., illustrate very well the impossibility of submitting plans and reports to Washington and awaiting decisions and preparation of bills of material in the Washington office. When the writer arrived on the ground on July 16th, 1917, the site for the camp was not yet selected, although arrangements had been completed by the local Chamber of Commerce for the purchase of a large tract of property which offered a number of possible locations for a divisional camp. Within the ensuing two weeks, the site was selected, the general plan of the camp outlined, railroad connections arranged for, and construction on the first unit started by the contractor. During the same time, a decision was reached to secure a water supply by connection to the mains of the water company supplying the City of Anniston, by the construction of a booster station and reinforcing and supply mains, 32 000 ft. in length. About August 1st, word was received that water must be made available in the camp for the troops who would commence to arrive on August 15th. The delivery and distribution of the pipe commenced the same day; pipe-laying started on August 4th; and although two days of rain intervened, on which no pipe was laid, the line was tied in and an ample supply of water for the first troops delivered to the camp by August 15th.

Some further facts about this water supply system are of possible interest, as illustrating the extent to which the design and construction were controlled by conditions other than those which would apply in ordinary practice. The source of supply of the water company supplying the City of Anniston is Coldwater Spring, a great spring gushing out of the limestone and said to have a flow of 25 000 000 gal. per day. Water taken from this spring is pumped to a distributing reservoir at such an elevation as to give a static head at the camp site of more than 50 lb. per sq. in. The largest size of pipe which there was any possibility of obtaining within the requisite time, however, was 10 in. in diameter, and this size was selected on the basis of possible deliveries, without regard for the fact that theoretical computations appeared to indicate that a larger size might have been more

economical. With this size of pipe, it was estimated that at the assumed maximum daily rate of draft —1 500 000 gal.— a pressure of not less than 30 lb. per sq. in. could be maintained at the site selected for the location of a booster station, which would be sufficient to maintain domestic service to the sections of the city and suburbs dependent on this portion of the distribution system; and that by raising the pressure at the booster station to 130 lb. per sq. in., this quantity could be delivered to the camp with a resultant pressure at the camp site of 50 lb. per sq. in. Mr. Scharff.

Another feature of the water-works system at Camp McClellan, which was controlled entirely by the time limit set for completion, was the location of the 10-in. supply main which followed, for the greater portion of its length, the existing tracks of the Southern Railway and the connecting line constructed for the service of the divisional camp. A location approximately 4 500 ft. shorter would have been available by following some of the existing country roads, but as these roads were practically impassable for heavy traffic, it would have been impossible to complete the delivery of the pipe within the time limit fixed by military necessity.

The rapid delivery of the pipe required by this 32 000-ft. supply main and its completion and connection within 10 working days, must be ascribed largely to the authorization by the Washington office of the use of cast-iron pipe and to the co-operation of the Superintendent of the Anniston foundry of the United States Cast Iron Pipe and Foundry Company. This company furnished from its Anniston, Chattanooga, and Bessemer foundries all the pipe in the line, except about 5 000 ft. of Universal pipe, and when completed, the line contained in addition to the Universal pipe, standard bell and spigot pipe of Classes A, B, C and D; standard gas pipe of two weights; and several thousand feet of 9.8-in. (25-cm.) pipe of special quality, which had been cast for the Argentine Republic. Not only did the foundry superintendent devote a large part of his time in securing these deliveries, but, in addition, he arranged for the use of the foundry pipe crane, much of the time under his personal supervision, to distribute more than 20 000 ft. of pipe along the trench from the railroad, with maximum rapidity and minimum breakage.

The service of the Anniston foundry was also of the greatest value in securing the rapid delivery of special castings and even of flanged castings. On one occasion, while additional pumps were being constructed in the Coldwater pumping station of the water company, a crack was discovered on a Sunday afternoon in a 16 by 10-in. reducer. The superintendent of the foundry was reached on the telephone, and, on Monday morning, the completed casting, faced and drilled and still hot from the moulds, was delivered at the pumping station over

Mr. Scharff.

8 miles of country road. This service permitted the casting to be placed in position and pressure restored by 4 P. M. on Monday.

The early operations of the water-works system at Camp McClellan produced interesting examples of the difficulties, due to the peculiar character of water consumption in military encampments. The pressure from the city distributing reservoir was sufficient to deliver the quantity necessary for night use and the requirements of the first troops which arrived on August 15th, without booster pumping; but after the completion of the construction of the first booster pump, on August 19th, it was necessary to operate the booster pumping station throughout the day, every day, from about 5 A. M. to 7 or 8 P. M. This method of operation was sufficient to permit the continuous maintenance of satisfactory service after the completion of the camp distributing reservoir on October 13th; but, until that time, much difficulty was experienced in maintaining service, due to rapid fluctuations in pressure resulting from the large variations in hourly use. Prior to the completion of the reservoir, it was found to be impossible to maintain pressure in the higher parts of the camps immediately after the noon mess hour, when the mess kits were being cleaned, and for the greater part of Wednesday and Saturday afternoons when there was no drill and when most of the showers in the camp would be found running either for bathing or washing purposes. These difficulties were especially great during the period from August 19th to September 11th, when the booster station was pumping into a closed system, not only without storage, but without adequate pressure relief. During this period, a direct telephone connection was maintained between the booster pumping station and the engineering office at the camp, and during certain portions of the day, an observer was stationed at each point watching the pressure gauges, the observer at the camp directing the operation of the suction valve on the pump so as to control the pressure at the camp. In spite of this precaution sudden pressure jumps occurred on several occasions, and breaks in the supply main resulted once or twice.

On September 11th, a pressure regulating stand-pipe of 10-in. pipe supported by a wooden scaffolding, was constructed and carried up to the elevation of the distributing reservoir (then under construction). At the top of this stand-pipe, an elbow and a 6-in. valve were leaded in, and this overflow at the highest point of the system proved a reasonably effective pressure regulator, although at times, some attention to the pressure gauge at the camp and control by regulation of the suction valves at the booster station were necessary.

In some respects, there was much similarity between the cantonment water supply work and that on which the writer was subsequently engaged in the Water Supply Division of the Office of the Director of Construction and Forestry of the American Expeditionary Forces in

France. In both cases, the time element was of far greater importance than the ordinary considerations controlling engineering design. In one respect, however, the cantonment construction work was very much more satisfactory and enjoyable than that in France. Reference is made to the availability and orderly rapid delivery of material made possible by the efficient co-operation of the Washington office, as compared with the discouraging impossibility of securing materials, which resulted from the tonnage shortage during the early days of the history of the American Expeditionary Forces. Mr. Scharff.

SAMUEL A. GREELEY,* M. AM. SOC. C. E. (by letter).—All who served as supervising engineers for the construction of the National Army camps, will feel grateful to Col. Maury for his excellent and generous paper on the water supply work of the Construction Division. The writer's work was at Camp Custer, Mich., in 1917, as Consulting Engineer, in charge of the water supply and sewerage, and, in 1918, as Supervising Engineer for a 40% extension to the camp, which brought its total capacity to about 50 000 troops. It is thought that some additional data having particular reference to construction and operation will prove helpful, with a reference to several more detailed descriptions. The writer's connection with both construction periods enabled him to acquire a perspective after the first rushing season of 1917 and prior to the second period which began in August, 1918. Mr. Greeley.

He first visited the site of Camp Custer on June 12th, 1917, and several days later sent a preliminary report to Washington covering the water supply, sewerage, highways, and railroad connections. On June 29th, he went to Washington for a conference. The helpfulness of the Advisory Engineer for Water Supply and his staff was thus early discovered, and thereafter this assistance was sought from time to time through conference and by correspondence.

Organization.—It was realized during the 1917 experience that a clear-cut organization with definite responsibilities was of paramount importance in expediting the work. This organization was definitely accomplished in 1918. The office of Executive Engineer was especially helpful, as it handled all office details, including matters relating to personnel, reports, weekly meetings, transportation, and the like. At the start each division engineer was given definite instructions relative to keeping permanent records of the work as built, cost records, and data for reports to Washington. This all helped greatly in finally winding up the work.

Progress.—It was also found that complete up-to-the-minute progress records were essential to finishing the work on scheduled time and to maintaining pressure where it was most needed. A special progress department of three engineers was formed. The duty of this depart-

* Chicago, Ill.

Mr. Greeley.

ment was primarily to receive, tabulate, and correlate the daily progress records of the various divisions. Daily reports were submitted by the divisions to the Progress Engineer, which he charted for the Constructing Quartermaster and the Supervising Engineer. From these charts, weekly reports were prepared for the Washington office.

The analysis of progress from day to day was based on time-labor rather than on cost, and cost summaries were carried separately. This was done to meet the war demand for rapid work. The estimated relation between time-labor and cost for the various divisions of the work, as used on the Camp Custer Extension (1918), is given in Table 2.

TABLE 2.

Division.	Percentage of Total Work:	
	Time-Labor Basis.	Cost Basis.
Buildings	63	77.4
Water supply	12	9.5
Sewerage	10	3.1
Roads	7	3.35
Railroads	5	3.35
Outside electrical	3	9.3
Total	100.0	100.0

A daily general progress chart was posted, showing the essential elements. The linear feet of water pipe, sewer pipe, and concrete road built each day showed the future rate of progress necessary to completion by a given date and assisted in determining the number of trenching machines needed, etc. The delivery of materials also influenced this feature.

The Progress Engineer was also called on to keep in touch with the inspection of the work, so as to afford an outside disinterested check on each division as to progress and workmanship.

Sanitation.—Col. Maury mentions the epidemic of influenza as one of several items which combined to increase the cost of the work. The extension to Camp Custer was started just as the influenza began to develop in the Middle West. To reduce it as much as possible, and to maintain the construction camp in a clean, healthy condition, a division of sanitation was organized. The results were gratifying. From October 6th, 1918, when the working force was 1 281, to November 15th, 1918, when it was 2 572, there were 4 cases of influenza and 1 case of pneumonia, and altogether only 14 cases of sickness requiring the attention of a physician. At this time, 65% of the work was completed. From November 15th to December 31st, 1918, when the working force fell

from 2 572 to 1 080, and 90% of the work had been done, only 10 more cases of sickness occurred. This was accomplished by active attention to all the details of sanitation, including water supply, bunk houses, stables, restaurants, cleaning of grounds, personal cleanliness, etc. In connection with the water supply, a quickly set-up drinking fountain, of which fifty were placed about the work, was used. During the active period of construction the sanitary squad comprised 80 men, of whom 23 were on night duty. It is believed that these results not only maintained a good working force, but also increased applications for work as the healthfulness of the construction camp was well known in labor circles throughout Michigan and the adjoining States. Mr. Greeley.

Construction.—The water distribution system was built almost entirely of wood pipe. In 1917, the bells of all cast-iron fittings were ground to fit the tenons of the wood pipe. During 1918, standard fittings with lead rings were used. The bulk of the trenching was done by machine, the average rate of progress in 1918 being 342 ft. per machine day. The work was slowed up by the difficulty of securing cast-iron fittings. On the completion of a section of the distribution system, the pipes were flushed and "hypo" was pumped in until bacterial analyses showed the water to be safe.

At the pumping station, the principal feature of the 1918 work was the erection and cutting in of new units without interrupting the service. This was done with a total shut-down of 53 min., during which time the camp was supplied from storage. Two motor-driven and one gasoline-engine-driven centrifugal pumps were installed and connected to the wells built in 1917. As nearly as could be ascertained, the cost of 8 and 10-in. wood mains in 1918 was $2 per ft.

Operation.—One of the satisfactory features of the camp work was the opportunity of putting the works into operation. At the close of the 1917 construction period, tests of the centrifugal pumps were made and characteristic curves drawn. An operating outline was thus determined. In addition, a chart was prepared for recording daily the camp population, the coal consumption at heating plants, and the water consumption daily and per capita. A study of fixture losses in lavatories was made, and a preliminary list of items for the regulation of consumption was prepared.

Summary.—The writer believes that the construction of the camps was well done, all things being considered, and that one of the outstanding features was the use of the country's engineering resources, marshalled and directed through the Washington office, as outlined by Col. Maury. No serious errors have appeared.

LYNN E. PERRY,* ASSOC. M. AM. SOC. C. E. (by letter).—The Society is much indebted to Col. Maury for this valuable paper. Indeed, the Mr. Perry.

* Easton, Pa.

Mr. Perry.

country is indebted to him and his capable and patriotic corps of assistants comprising the Construction Division of the Quartermaster Corps.

Considerable courage was needed to adopt so low a per capita daily consumption of water as 55 gal. The writer is positive that not many data were available concerning the water consumption of a soldier as contradistinctive to a civilian; and it could only have been Col. Maury's extremely broad experience and ripe judgment that led him to adopt so economical and, at the same time, so adequate a figure.

The writer's experience with the water problem at the large cantonments in the United States has been that of consumer only. He was, however, for a short time associated with the Aviation Section of the Signal Corps at one of the fields under construction. This field was designed for six aero squadrons and proportionate medical and quartermaster detachments, a total of about 1 018 officers and men. The maximum population during the writer's stay was 1 066.

The water supply was lifted from four wells, about 300 ft. deep, into a concrete reservoir; thence, it was pumped to a tank 135 ft. high. Aviation fields are usually located on fairly level sites, and this field was no exception. A geological investigation indicated that the water entered the stratum at an outcrop about 40 miles north of the field; the quality was good.

During construction the engineer was persuaded to sink one well to a lower stratum, the quality of the water from which was known to be excellent and was being used by a near-by large city. The well, however, would yield only about 67 gal. per min. and was drawn to the shallower stratum, the orders being to sink four wells each yielding 100 gal. per min.

Thus, four wells were provided, each yielding 100 gal. per min., or a total capacity of more than 500 000 gal. per day, for a population of about 1 000. Either well would supply 140 gal. per capita per day which, incidentally, was about the consumption. The entire system was constructed of cast iron and the tank was made of steel. Although the writer advised an emergency chlorinator, none was provided during his stay. During construction, when an inferior quality of water was being used, an emergency hypochlorite plant had to be provided.

The writer's attention was particularly drawn to the sanitary precautions mentioned in the paper. He has always been an enthusiastic advocate of emergency chlorinators, especially where the water is of questionable quality, and believes that these were finally provided at all the cantonments and camps in this country.

The covering of reservoirs and tanks to prevent pollution and the growth of algæ is also very important. The writer had considerable difficulty in obtaining materials for this purpose in France; at least

one reservoir, that for the Kerhuon Hospital Center, near Brest, was covered with canvas, after having been in use for about one year. Mr. Perry.

It would be instructive and interesting to have a discussion from some one connected with the Construction Division of the Signal Corps, in connection with the experience and activities of that body during recent hostilities. A paper presenting the work of the Water Service in France would also be timely, and the writer trusts that such a paper will be written.

ASA E. PHILLIPS,* M. AM. SOC. C. E. (by letter).—In the discussion of this admirable paper on water supply for camps and cantonments, which only briefly outlines the great work done by Col. Maury and his staff, there should be recorded, with just estimate of its paramount value, the remarkable rapidity with which results were achieved in completing and putting into operation safe, adequate and reliable water supply systems for these extraordinary military establishments, which results could only have been accomplished by rare good judgment, reinforced by instant decision and exceptional foresight. In reading this paper one gets only a glimpse between the lines of these qualities on which the success of this great work depended so completely. Mr. Phillips.

Perhaps one of the war expressions that will linger longest in the minds of many is "quantity production"—so often a Utopia not reached until after Armistice Day. It should be recorded, however, in the annals of Engineering, that of all war activities none approached the great achievement of the Construction Division of the War Department in instantly striding into quantity production from the day the organization was set up; and this could only have been due to the extraordinary quality of the personnel of the commissioned officers on Gen. Marshall's staff. In the remarkable results achieved, Col. Maury contributed much, and that was of vital significance.

In many ways this work on the water supply for cantonments and camps is of permanent value. The wide experience it has given in the use of wood-stave pipe, in standards of lay-out and construction, in safeguarding water supply, and enlightening work in the way of fire protection, has left the leaven of sound practice in the far reaches of the country.

Thus far, much of the discussion on this paper has been devoted to consideration of the unit allowance of 50 gal. per capita per day, and, occasionally, there occurs a lament at the average per capita daily consumption of the larger cities. "One of the greatest economic municipal crimes of the United States", says P. H. Norcross, M. Am. Soc. C. E., in his discussion, "is the extravagant use of water. In no city is this emphasized more acutely than in Washington, D. C., where the

* Washington, D. C.

Mr. Phillips.

daily consumption runs as high as 150 to 160 gal. per capita, and where practically 60% of the total water furnished is used by Government Departments, for which no direct charge is made. The remaining 40%, which is used by the private consumer, bears the entire burden."

There is much truth in what Mr. Norcross says, and yet his data set forth the situation so imperfectly that it may be well to record, as accurately as is now possible, some figures as to water consumption at Washington. The average daily consumption for the fiscal year ending June 30th, 1919, was 64 428 356 gal. distributed about as follows:

Domestic (dwellings and apartments), 88% metered	20 000 000 gal.
Large private consumers, all metered	12 000 000 "
Municipal buildings and works	3 500 000 "
U. S. Government	25 000 000 "
Unaccounted for	3 900 000 "

From this it will be seen that the domestic consumption is 31% of the total, large consumers 19%, municipal 5%, and the U. S. Government, 40 per cent. The domestic consumption is about 45 gal. per capita, and the total consumption about 142 gal. per capita.

The total revenue from water rates for this fiscal year was $782 159.36, derived about as follows:

Domestic (dwellings and apartments)	$560 000.00
Large consumers	222 000.00
Municipal	None
U. S. Government	None

Thus, it is seen that the domestic consumers pay 72% of the total tax for 31% of the water; the large consumers pay 28% of the tax for 19% of the water; and the United States pays nothing for 40% of the water.

Now, it is quite apparent from these figures that Washington can lay no claim to pre-eminence in the category of "municipal crimes" of this character. Whatever there may be of undue usage of water, it certainly cannot be charged to the domestic consumer, who modestly pays three-quarters of the tax and receives one-third of the water, or to the municipality.

With this unbalanced adjustment, if it were not for the revenue derived from the large consumers, sufficient funds would not be available to operate the Water Department, and, perhaps, this condition has permitted somewhat greater liberality as to usage by the large private consumer, the only other source of revenue, since the United States declines to pay anything. As a tax on municipal use must come from the taxpayer, and only means taking money out of one pocket to put it into another and but little increase in revenue would be had in this

way, it presents small opportunity for relief, although doubtless sound in principle. Mr. Phillips.

The only large manufacturing establishments in Washington belong to the United States Government. Of these, the Naval Gun Factory, the Government Printing Office, and the Bureau of Engraving and Printing use about 40% of the total Government consumption, the remainder being used in other Federal establishments, such as hospitals, laboratories, and offices. Much of this usage may well be considered wasteful, but the total must inevitably be large.

Probably no other city in the country has a more evenly distributed domestic consumption throughout its population, so that the average daily domestic consumption must be considered to be quite low, when one takes into account the character of the population, as well as the physical characteristics of the National capital.

DABNEY H. MAURY,* M. AM. SOC. C. E. (by letter).—Mr. Dunham asks whether, with the experience thus far gained, the writer would, on a similar demand for advice to the Government, recommend the same per capita allowance. To this the writer would unhesitatingly reply that, under similar conditions, he would. This answer should not, however, be construed to apply without exception to all sorts of Government activities, in peace as well as in war. Mr. Maury.

In time of peace, restrictive regulations and military discipline generally are apt to be less rigidly enforced than in time of war. Furthermore, in time of peace it is exceedingly unlikely that any army post would be garrisoned to its full capacity, and it was observed in every case that as the number of men at any camp was reduced, the per capita consumption increased, and *vice versa*.

The capacity of the water system should be great enough to give each man his proper daily allowance, assuming the camp to be fully occupied. Then, if a large number of men are ordered away, it is to be expected that the per capita consumption will increase, because all the leakage and part of the waste will continue as before; but there will still be enough water for the men remaining, and the increase in per capita consumption will not have nearly as bad an effect as would be the case if it resulted in an actual shortage of water.

It was the writer's observation that, as a rule, the per capita consumption at the older and permanent posts was extravagantly high, often several hundred gallons per day. This was due in part to the large quantities of water used for lawn sprinkling; in part to seriously defective plumbing, especially in Coast Defense Fortifications, where brackish water had caused many leaks; and in part to waste of water in the officers' quarters.

* Chicago, Ill.

Mr. Maury. What a man gets for nothing, he neither appreciates nor conserves. If all the officers' quarters were metered, with water furnished free to the amount of, say, 50 gal. per day for each occupant of the quarters, and a good stiff meter rate added for all water used in excess of that allowance, much could be accomplished in the way of reducing the consumption at these army posts.

The writer is well aware, however, that the enforcement of this regulation would add nothing to the popularity of the already much-abused Utility Officer, and that for a few days after rendering his monthly water bills, he might feel tempted to absent himself from the officers' mess and club.

In reply to Mr. Dunham's second question, the writer would state that the water-works systems of the cantonments were designed to furnish, in addition to one-quarter of the peak rate of domestic consumption for a fully occupied camp, water for fire purposes at the rate of 2 000 gal. per min., at a net pressure of not less than 50 lb. per sq. in., at any group of hydrants on the distribution system. The fire-drill regulations made it the definite duty of certain designated individuals to shut off, as soon as the fire alarm was sounded, every fixture from which water might be drawn for purposes other than fire-fighting, except those necessary for cooking purposes. There were two principal mains, 480 ft. apart, running through each regimental unit, with hydrants spaced only 215 ft. apart on each main, so that twelve streams could be concentrated on any building between the mains, without laying any line of hose longer than 350 ft. The shortness of the lines of hose and the use of small hose nozzles, only ¾ in. in diameter, combined to give very small friction losses through the hose. There was good separation of buildings—40 ft. between two-story buildings, and 30 ft. between one-story buildings or between a one-story and a two-story building. There were also fire gaps of 300 ft. between brigade units or groups of buildings. Plenty of men were available, of course, to handle the hose and the hydrants.

The net effect of all these specifications was that any building could be attacked from many different directions by a large number of fire streams, with good nozzle pressure and good horizontal projection of stream. The results obtained in extinguishing fires and in keeping down fire losses were summarized in the paper.

Mr. J. Waldo Smith asks whether the writer would recommend the form of contract used in building the cantonments for general adoption in time of peace.

That form of contract was unquestionably the only one under which the cantonments could have been constructed within the time allowed. Its development was almost a stroke of genius on the part of the members of the Advisory Committee referred to by the writer; and this is especially true if genius be defined as "an infinite capacity

for taking pains", for that contract represented weeks of the most careful study by some of the brightest minds of the Profession. Mr. Maury.

The writer, however, concurs in Mr. Smith's opinion that the cost-plus-a-fixed-fee contract is not one which should be adopted generally for all construction in time of peace, and especially where speed is not of vital importance.

In conclusion, the writer fully realizes his good fortune in having had his paper discussed by so many of his personal friends, and he would again remind his readers that the design and construction of the water-works for the army activities were in no sense a one-man job, and that the credit for such results as were obtained should be shared by all the many men who had a hand in the work.

Paper No. 1436

AMERICAN HIGHWAYS

AN INFORMAL DISCUSSION AT A MEETING OF THE SOCIETY, APRIL 16TH, 1919.

BY MESSRS. W. G. B. THOMPSON, H. ELTINGE BREED, EUGENE W. STERN, CALVIN TOMKINS, H. F. DUNHAM, AND WILLIAM E. WOOLLEY.

Mr. Thompson.

W. G. B. THOMPSON,* ASSOC. M. AM. SOC. C. E.—The population of what is generally known as the metropolitan district of New York is, at present, approximately 7 000 000 people, and is rapidly increasing in volume and density. This district may be said to embrace Brooklyn, Queens, Richmond, Manhattan, the Bronx, and the territory of New Jersey lying between the Hudson and Passaic Rivers.

Approximately, 30 000 miles of railroads have their termini on the New Jersey side, and seventy or more steamship lines operate from the joint port to all parts of the globe. Traffic and freight transfer conditions are daily becoming more difficult to handle, economically and expeditiously, and, unless an immediate and serious effort is made to devise a general plan or scheme which will co-ordinate all the factors in the problem in a manner to afford early relief, with ample provision for indefinite future expansion, not only the supremacy of the Port of New York will be endangered, but the very existence of its people (especially on Manhattan Island), may conceivably be threatened. This was exemplified during the winter of 1917-18 when severe weather and ice prevented coal movement by water to the city, and during the recent strikes of harbor boatmen, when coal and food supplies were threatened, and thousands of workers were unable to proceed to their offices and shops, due to the ferry systems being tied up.

It will be especially interesting to note the effect on the daily supply and life of the city in connection with the general harbor strike called

* Trenton, N. J.

Mr. Thompson.

for April 15th, 1919, when 16 000 men may quit work because of differences with employers. According to the plans of the strike leaders, not a single exception is to be made in favor of any class of harbor activity. The leaders claim that unionists will quit Army and Navy craft, except where manned by enlisted service men. They will also quit all railroad ferries and, it is reported, will refuse aid in berthing hospital ships from abroad. They propose, also, to attempt to tie up coastwise and transatlantic shipping, and to try to enlist the Sandy Hook pilots. The strike is also aimed at the Railroad Administration. If effective with regard to that organization, a serious menace to the coal supply of New York is in sight.

The speaker will not discuss the merits of the proposed strike or the conditions which make possible such a deplorable state of affairs, where a comparatively small body of men may actually endanger the physical existence and paralyze the economic life of a city of 3 000 000 people in order to satisfy their own particular desires. Such conditions give added emphasis to the idea that the development of New Jersey's highways to their highest efficiency and the construction of vehicular tunnels under the Hudson River are intimately connected with the future welfare of New York City.

The construction of one or more vehicular tunnels under the North River, if such tunnels are wisely designed to provide for future increase in vehicular traffic between New Jersey and New York, will go far toward removing the possibility of a future food shortage in New York City.

It is granted that freight and foodstuffs may be brought from Long Island, from New England, and from the West, *via* Buffalo and the Poughkeepsie Bridge, which in a measure would alleviate conditions arising from a future tie-up of harbor transportation; it is a fact, however, that by far the greater proportion of the food and daily necessities of New York City come through the freight-yards on the New Jersey shore, and that even a slight interruption in the continuous flow is serious, when it is considered, as has been asserted, that Manhattan Island has but 7 days' supply. It is also admitted that coal and other freight may be brought through the Hudson River Tunnel to the Pennsylvania Railroad Station at 34th Street and Seventh Avenue, but the passenger terminal lacks adequate facilities for freight handling, and cannot be considered an important factor as a freight-receiving and distributing point without serious interruption to the passenger traffic; therefore, development of means of vehicular transportation between New Jersey and Manhattan Island at an early date is imperative. Relative to this matter, it is interesting and gratifying to note that Governor Edge of New Jersey and Governor Smith of New York have signed bills which will enable preliminary steps toward actual construction to be undertaken.

Mr. Thompson.

It is well known that the present ferry system is incapable of handling the vehicular traffic expeditiously. Long lines of trucks now stand many hours awaiting their turn to cross the river from both sides, and the delay, being costly to all concerned, naturally affects most heavily the ultimate consumer. Statistics, compiled in connection with an investigation made by the Public Service Corporation of New Jersey, show that 6 130 945 vehicles of all classes use the North River Ferries between 130th Street and Cortlandt Street annually. These figures are based on an average week-day record, multiplied by 300 for week days, and a Sunday record multiplied by 65 for Sundays and holidays.

The normal increase in vehicular traffic is estimated to be between 3 and 5% per year. Considering this fact, and, further, that the ferries are now unable to handle the traffic, that the possibilities of further expansion of the ferry service are exceedingly limited, and that, even if the ferry terminals could be extended, the North River is now overcrowded with craft of every description, it is evident to men who have studied the matter seriously that at least one tunnel should be constructed as soon as possible.

It is estimated that 2 000 000 vehicles per year will use the tunnel. It is evident from these figures that the present congestion and long waits at the ferry entrances will be reduced very materially, if not obviated altogether. How long the proposed tunnel at Canal Street will serve properly the needs of cross-river traffic is a matter for conjecture. Mr. Edward R. Viets, of the Service Recorder Company of Cleveland, states that the number of motor trucks increased from 60 000 in 1912 to 600 000 in 1918. As the increase in the use of motor trucks follows rapidly the construction of good roads, and the greatest road construction period the country has ever known is just opening, it is reasonable to assume that the annual increase in the number of trucks will be as great during the next 6 as during the past 6 years. As a consequence of this, and the natural increase in volume of business within 30 miles of New York City, one may reasonably look for a recurrence of the present congestion by 1928, if not earlier; it would seem, therefore, that even before Tunnel No. 1 has been completed, consideration should be given to investigating a site for Tunnel No. 2. There is ample precedent for such action when one considers the East River. Considerable courage was required to start the construction of the Brooklyn Bridge. Not very many years after its completion came Bridge No. 2, then Bridge No. 3, and then Bridge No. 4. The capacity of these bridges is now sometimes severely taxed, notwithstanding that there are many ferries plying between Brooklyn and Manhattan Island. The population of Brooklyn is approximately 2 500 000. The population of New Jersey in the metropolitan district is approximately 1 500 000. Consider these facts, and, further, that the construction of Hudson Vehicular Tunnel No. 1 will facilitate and

stimulate business to such an extent as to increase rapidly the population of metropolitan New Jersey, that there will be created the same conditions which made necessary the construction of additional bridges over the East River. The completion of the present New Jersey Highway System, and its further extension as finances and conditions warrant, will but add to the burden converging on the Hudson River between 42d and Cortlandt Streets. Mr. Thompson.

It does not require a long stretch of the imagination to picture New Jersey's highway system as playing an important part in keeping New York City supplied with many necessities, especially when freight terminal congestion (which is inevitable at such an ill-equipped port) makes the handling and lightering of New York City and foreign freight difficult and tedious, more particularly in winter. Just a word as to the scope of this highway system as now laid out: The State Legislature of 1917 created a State Highway Commission of eight members, two of whom are members of this Society, and six of whom are well-known business men. There was also established a State Highway System, comprising 655 miles of the main traveled routes of the State, which serve well its industrial and agricultural regions. They are all tied together, and, in effect, radiate from or terminate on the New Jersey shore of the Hudson. Owing to its geographical position, New Jersey is the throat through which must pass all traffic from New York and points east to Philadelphia and points west and south. An unusually heavy burden of foreign traffic is thus imposed on the highways between the Hudson and the Delaware at Trenton. As an indication of its volume and weight, a traffic census taken early in 1918 showed a total daily weight of approximately 7 900 tons, including vehicles, freight, and passengers on a part of the Trenton-Newark highway between New Brunswick and Elizabeth. This is for one route only, and is an indication of the potential value of the highway system as a supplement to the railway system, especially considering the rapid increase in the number of motor trucks, which will follow the construction of pavements adequate to sustain them. Within one year there will be hard, smooth pavement on good alignment and easy grades, from the Hudson to the center of New Jersey's richest agricultural district. This will make possible direct trucking from farm to market or consumer. Even now, fruits and vegetables are trucked from points south of Trenton to the New York market daily. The completion of the tunnel will enable this produce to proceed uninterruptedly to New York, instead of waiting many hours for ferry passage.

In order to provide a highway for traffic to and from Hudson River points without passing through the congested Newark streets, the Counties of Essex and Hudson, with aid from the State, are now making investigations looking toward the construction of a highway bridge over Newark Bay between Bayonne and Elizabeth, by which

Mr. Thompson.

vehicular traffic may reach the Hudson County Boulevard, and thence go directly to the tunnel and ferries, shortening the motoring time between Elizabeth and Jersey City by at least 30 min. The State Highway Commission, in building a new road over the Palisades to Fort Lee Ferry in Bergen County, is doing much to relieve the congestion at the lower river ferries. The major portion of truck traffic from the Passaic and Hackensack Valley industries must now use the down-town ferries. The proposed new approach will provide a direct route from Paterson to 130th Street, New York City. The grades will not exceed 6.5%, and will be much lighter than on any present approach over the Palisades to the ferries. This will also enable heavily loaded trucks, bound to or from upper New York State, Connecticut, and Massachusetts, to avoid down-town New York City, when en route to or from New Jersey and Pennsylvania points.

The completion of State Highway Route No. 9 will open a direct smoothly paved road from New York to the Delaware River at Easton, Pa., whence there is a fine paved highway to South Bethlehem. As a peace time highway, this will have great commercial as well as scenic value. As a war time highway, its value would be inestimable, as it would connect the great Schwab plants directly with the Port of New York.

All the great industries of the Delaware River as far south as Wilmington, Del., will be connected directly with New York City by hard, smooth highways, by the autumn of 1920. It is said that all roads lead to New York. It is certain that New Jersey's highway system leads traffic to the Hudson River in an ever-increasing stream. The Highway Commission is constructing only the most durable pavements, which, in effect, will be city streets traversing the entire countryside, bringing the farms and producing centers ever in closer touch with the large cities. New Jersey contemplates spending approximately $6 000 000 during the summer of 1919 on State highways alone, in addition to which the counties will spend approximately $2 000 000 for new construction. As a sidelight on highway development as an adjunct or supplement to future railway development, the speaker quotes from a recent statement by C. A. Morse, M. Am. Soc. C. E., of the United States Railroad Administration:

"The perfection of the motor truck and tractor, together with the universal use of the automobile, has introduced a new element into the transportation problem that should be taken into consideration at this time, while studying the reorganization of the whole transportation question. Good roads are demanded for the use of the automobile, and a study should be made to see what additional expense would be necessary to construct them so that they would serve for motor truck and tractor. Where, heretofore, development of the country for 50 miles on each side of a trunk line of railroad has required the construction of light branch lines, it is a question to be seriously considered whether

this policy should be continued or whether good wagon roads should be constructed and the products of farms, and passenger travel, should not be handled by motor trucks and automobiles to the main line. Taken alone and considered as a unit, practically none of these small branch lines pays expenses, but as gatherers of freight and passengers to increase density of traffic on the main lines, they are sources of profit. As, however, the traffic gathered by them is turned over to the main line with a deficit attached, which has to be overcome during the main line movement before any profit is made, it would be a decided advantage if this traffic could be delivered to the trunk line by means of the motor truck, tractor, and automobile without this bill of expense attached." Mr. Thompson.

Noting the fact that thus one handling would be obviated, as it is now necessary to truck farm products to the short-line branch, and then transfer them to the main line, Mr. Morse continued:

"Investigation of this subject may show the desirability, as good roads are completed, of taking up many branch line railroads and utilizing the abandoned roadbed for improved motor roads, thus decreasing the expense of maintenance and operation of our railroads and giving in its place a well located motor road. Such a change would call for increased facilities at stations along the main line for passengers and for hauling freight, including storage, trackage, etc., but it would mean the concentration of supervision and labor, permitting better housing and living conditions for employees. Motor-driven conveyances have gradually been changing conditions of railroad transportation for the past ten years, and now that the general study of transportation facilities is up for discussion, it should be taken into careful consideration and due weight given to its influence on the economies of the situation."

From these quotations it will be seen that railroad managers are seriously considering the question of leaving to the highways the matter of caring for short-haul freight. Such a system would obviate the construction of short feeder lines, costly rehandling of freight, and result in more rapid delivery.

The motor vehicle laws of New Jersey are now very well defined. The maximum load allowed is 30 000 lb., assuming that approximately 75% of that load is carried on the rear axle. The speaker thinks that is higher than is allowed or contemplated by most States. The tire equipment is also regulated in accordance with the weight of the machine. The speaker thinks that the maximum now allowed is 800 lb. per in. of width of tire.

The regulations of the Motor Vehicle Department also restrict the height of trucks to 12 ft. 6 in., and the maximum width to 8 ft. The traffic regulations are also about to be enforced more rigidly, in order to provide greater safety on the highways. The Motor Vehicle Commissioner has fifteen or twenty inspectors who are patrolling the roads

Mr. Thompson. constantly, in order to protect the careful driver against infractions of the regulations.

The question of determining a standard or a set of standards for the regulation of motor trucks to restrict their weight, size, and speed, is now under way, a committee having been appointed by the National Highway Traffic Association. This committee is composed of five State Highway Engineers and four representatives of the motor truck manufacturers and users.

The matter came up for report at the Annual Meeting of the American Road Builders' Association, held in New York City, in February, 1919, when the committee made a Progress Report to the effect that the weights of motor vehicles should be restricted arbitrarily to 28 000 lb. gross weight of truck and load.

That met with considerable opposition, because of the fact that at present the statutory requirements in a number of States are much lower, running down to 24 000 and 20 000 lb. gross load. The question is debatable, as the decision depends entirely on arbitrary conclusions, because there is no definite data to determine how much more damage may be done by a 28 000 or a 30 000-lb. load than by a 5 000 or 10 000-lb. load; but it is hoped that during 1919 a common standard will be accepted, at least, for the North Atlantic and the Eastern States of the country, where the truck traffic is now the heaviest.

Probably the matter will be settled eventually on a basis of about 25 000 lb. That was demanded by the highway builders and highway authorities, and an attempt was made to show to the motor vehicle owners and motor vehicle manufacturers that unless there was an arbitrary decision, the agitation in communities having to pay for those roads would be such as to compel them to adopt a lower standard. For example, the Legislature of Pennsylvania had a bill before it restricting the weight to 24 000 lb., which would have compelled trucks which could be used in New Jersey up to 30 000 lb. to stop at the Delaware River; and, of course, that would interfere with the free movement of interstate truck traffic.

New Jersey's law is in operation now, and an effort is to be made—a very effective effort—to see that trucks do not exceed that load, because the inspectors will compel the weighing of occasional trucks which seem to be too heavy. If they are over weight, the owners will be fined for disobeying the law.

Mr. Breed. H. Eltinge Breed,* M. Am. Soc. C. E.—The present is the point of departure. Before discussing concrete details of future development, an attempt will be made to state briefly the present conditions. The war has given a tremendous impetus to all the sciences. The economic situation stresses to-day as never before the necessity for ampler, fairer methods of production and distribution. Engineers have a mass

* New York City.

of definite scientific data behind them, and the needs of a world before them. Mr. Breed.

Highway work has now reached the adolescent stage. Its infancy lasted more than 100 years, about 90 of which were spent in one long nap. Under Jefferson's administration the National Government and a number of the States started a road-building programme. The Government built a few hundred miles of roads and the States a similar number. Shortly after starting this programme, all road building on the part of the National Government and the States ceased. The work was then taken up by many turnpike companies, which built a number of roads in the Eastern States, operating them under the toll system. After the establishment of the toll road came the "nap". Road construction was handled principally by the township and county officials, with no development in types of construction or methods of maintenance, outside of large cities. This condition continued until the late Nineties. Then came the bicycle craze and active propaganda on the part of the League of American Wheelmen for better roads. Before this died out, the automobile had come to stay. As the number of cars increased, the great concern was the dust nuisance. Oil was applied and bituminous binders were used, but, almost before they were on, the old earth and light gravel roads beneath them had begun to disintegrate. The road builder's problem was growing, and he tried to solve it by constructing a better surfacing for the macadam types. That did not last long, as the increasing weight and speed of vehicles, and a few spring thaws and freezes, broke it up.

This also affected the taxpayer's money, for, by this time, the various States had taken up the matter of road building, with subsidiary county and township systems. In New York State the Legislature of 1898 passed two Acts, the Fuller-Plank Act, providing that the State would duplicate for each town whatever amount it raised for highway purposes; and the Higbie-Armstrong Act, appropriating $50 000 for roads to be improved—50% by the State, 35% by the county they were in, and 15% by the townships. Each year after that the annual appropriation for highway work grew, until, in 1904, it was $1 108 000. Yet there were only about 300 miles of even average good roads.

Some saw that it was time to call a halt, and cried, "This road building is no job for political henchmen; it is no game for amateurs. We need trained men. Give us university courses for Highway Engineers. Give us laboratories for experimental work. Above all, let us start at the beginning, plan our routes, abandon cow-trails, and build our roads from the bottom up."

That happened about 1903. Since then road engineers have been trying to keep up with traffic, like a child chasing a rubber ball down hill. They had almost caught it, when, suddenly, came the motor truck. Loads of 15 or 20, and even 30, tons were carried on roads designed

Mr. Breed. to endure 5 or 6 tons, and the roads broke down. Before this policy could be re-shaped, war was declared, and motor trucks were being built in great numbers in order to supplement the work of the railroads. Maintenance on the route along the east bank of the Hudson between New York City and Albany for 1917 cost $215 200.74, in comparison with an expenditure of $115 816.56 in 1915, showing an increase of almost $100 000, due to heavier motor truck traffic; but the roads were kept open for traffic, and there was no cessation of men and supplies between Buffalo and New York City. That, and the fact that to-day there are in New York State 7 200 miles of improved roads and 15 completed routes, north, south, east, and west, through the State, is a measure of the success attained. This, however, has been extravagant beyond measure, in money and energy, and has been smirched with failure. Politics have not been kept out of highway work. Some through routes lack important links, because, instead, spurs have been built to the homes of influential politicians. The work has not been kept out of the hands of amateurs—the roads are full of them, and will be until highway work pays bigger salaries and demands higher skill. Engineers have not done enough laboratory work. Instead, they have been prone lazily to trust the statements of the material interests, and this costly experience has not always been uncolored by commercial fiction. Only now are they beginning to understand what the term "foundation" really means.

The speaker has said that highway work has now reached adolescence: First, because a clear perception of the problem ought to mean that engineers have outgrown the errors of infancy.

Second, because public sentiment is solidly behind the idea. It has been created in the only real way, by the discernment of the people themselves that they must have good roads in order to be fully a part of the world in which they live, and has been formulated by the well-conducted campaign of good roads and automobile organizations, motor truck, and material interests.

Third, because the money has been provided, and more is coming. The Government has appropriated $200 000 000 as Federal aid to roads, and is planning to provide another $400 000 000 for National systems. New York State is on its second $50 000 000 bond issue. Illinois and Pennsylvania have just raised $50 000 000 and $60 000 000, respectively, and other States are rapidly falling into line. If these moneys are expended economically, no shortage of funds need be feared.

Fourth, because the people have reached the psychological condition which characterizes adolescence, namely, self-scrutiny and analysis.

What is meant will be explained in terms of types of pavement. On January 1st, 1918, there were, in New York State, 6 912 miles of pavement, of which 5 820 miles were non-permanent types and 1 092 miles were permanent; of the latter all but 129 miles were of brick or concrete.

The non-permanent types are water-bound macadam and bituminous macadam by the penetration method. Mr. Breed.

Water-bound Macadam.—This pavement is best adapted to the needs of light traffic, but has no place on any through route. It costs to-day about $23 000 per mile for a 16 to 26-ft. pavement, 9 in. thick (that is, a 3-in. top on a 6-in. sub-base). Low construction cost has been the greatest advantage. Its greatest disadvantage now is its high cost of maintenance, which, in 1917, amounted to $970 per mile. The average life of a pavement of this type is 7 years for a traffic of less than 1 000 tons per day. Many water-bound roads have worn out in from 1 to 3 years when required to carry a heavier tonnage.

Bituminous Macadam.—Penetration Method.—This type is also adapted to light traffic, generally, and is advantageous in many localities where the only stone available is non-binding. Among its disadvantages is its tendency to creep under traffic. It is slippery when wet; has a fairly high cost of maintenance—$412 per mile during 1917—and a construction cost of $28 500 per mile for a 16 to 26-ft. pavement, 9 in. thick (that is, a 3-in. top course and a 6-in. sub-base bottom course). The average life of this type is 2 years more than that of water-bound macadam under similar traffic conditions.

The determination given for the average life of the foregoing types was made in 1917. The much heavier traffic tonnage of to-day would shorten it considerably.

The following are classed as permanent types:

Concrete.—This pavement has the disadvantage of a glare. It has the advantage of low first cost—$31 200 per mile to-day for a 16 to 26-ft. pavement, with an average thickness of 6 in. Its maintenance in 1917 was $112 per mile. Its average life, thus far, can only be estimated, but, judging from the condition of pavements of this type, from 5 to 9 years old, with which the speaker is familiar, it is, say, at least 15 years.

Brick Pavement.—Brick pavements of the sand-cushion type have not been entirely satisfactory for country roads in this climate. One disadvantage is the shifting of the sand cushion, with the consequent settlement, breaking, and spalling of the bricks. The speaker cannot give present-day costs, as the State has ceased to build brick pavements, except as semi-monolithic and monolithic structures. The cost of maintenance was $222 per mile in 1917. The average life, of course, can only be estimated, but, from present indications, it might be placed at not more than 12 years.

Brick Pavements.—Semi-Monolithic Type.—This type differs from the original brick pavement, in that there is no sand cushion, the bricks being laid in a cement-sand bed and treated with cement grout so that the bed forms an integral part of the pavement. This type has the advantage of developing beam strength, as in concrete pave-

Mr. Breed. ment, and it eliminates the shifting of and depressions in the brick. Its cost under present conditions would be about $50 600 per mile for a 3-in. brick on a 4-in. concrete foundation. The speaker has no maintenance figures for this type, as the State has been building it for only a little more than a year.

Brick Pavements.—Monolithic Type.—This type differs from the semi-monolithic in that the bricks are set in a green concrete and treated with a cement grout so that it forms an integral part of the pavement. This type develops the full beam strength, and has even greater advantages than the semi-monolithic type, so far as strength is concerned. It is more difficult, however, to get as smooth a surface as can be obtained with the semi-monolithic type.

Asphaltic Concrete.—In order to insure a nearly smooth pavement, a smooth concrete foundation should be provided. These pavements have the disadvantage of pushing under traffic from future consolidation, if the aggregate is not properly sized and proportioned, or if it contains too much bituminous material. However, if too little of the latter is used, the pavement becomes dry and soon disintegrates. The ideal mix is one in which the motor oil dropped from cars renews the volatile oils lost. These pavements cost about $40 000 per mile (depending on the type), with a 2-in. top and a 5-in. concrete foundation. Their maintenance cost in 1917 was $245 per mile.

There are many patent pavements which come under the classification of permanent types and are good.

It is apparent that engineers know, with a fair degree of precision, what service such roads as these, built as they are to-day, will give under present traffic. With this knowledge, which was entirely lacking even 10 years ago, the speaker thinks they are prepared to emerge into real maturity. However, there is one proviso, namely, that no load on the roads shall exceed a given weight. In this restriction they should be guided, for 5 years at least, by the experience of the past. The slight chance that it may be a limitation is more than offset by the absolute assurance that it will be a safeguard to the roads.

The motor truck marks a distinct transition in transportation facilities. It has made the highway as available for freight haulage as the waterway and the railway. The service of the motor truck in the freight crisis of the past year established forever the importance of the highway as an integral part of the transportation system of the United States. Thus far, however, it has been fatal to the very factor on which its usefulness depends—it is the greatest destructive force the highway has ever encountered.

The latest traffic reports, on fifteen highways in various parts of New York State, show an increase in truck tonnage varying biennially from 50 to 400%, and, in 1918, an average increase of 150% over the

tonnage of 1916. To try to build highways to keep pace with a continuous advance of that kind would bankrupt the public. Mr. Breed.

The wiser motor truck manufacturers have themselves adopted the broad policy of selling transportation service, rather than the exclusive one of selling motor trucks. These men, who have had every opportunity to study the economics of the problem, have agreed on the desirability of the 5-ton truck as a standard unit. This should now be established by law, and the highways should be designed to meet it. It will mean a total maximum load of about 12½ tons, of which approximately 9 tons should be applied to the rear axle. There should also be general regulations for other destructive factors, such as inadequate tires and springs.

Engineers can build roads economically for the 5-ton truck, but cannot afford to have them disrupted by a few excessively large trucks. Nor should they be designed extravagantly to meet the requirements of a few individuals. The maximum loading must be restricted to the economic standard suggested by the manufacturers and desired by the majority of truck users. Then will the highway be able to give to the motor car and to the community its most efficient service.

Probably in every other line of engineering there is some such restriction, based on a fundamental and enduring economic law of relative values. Beyond that, however, engineers can plan for the future with imagination unfettered by any narrow limits of probability.

The speaker believes that the country, during the next 5 years, will be criss-crossed by myriad lines of communication: Waterway, railway, highway—the trinity of transportation, with great cities along the first two—centers of world-wide distribution, and feeding them, the highways with motor trucks incessantly going back and forth 10, 15, 20 miles, to centers of production, flourishing agricultural and industrial towns. Manufacturing will be more and more forced out of the big cities, through pressure of space, and into the surrounding country, where the much cheaper rentals will be more than an offset for the slightly greater carrying charges. Highway and motor truck make this feasible, and independent of railways.

Farming must be encouraged if the people are to live, and the speaker sees the highways as a great means of encouragement to the production of farm wealth. They will help banish from farm life its deadly isolation; they will make possible community towns, from which outlying farms may be worked. They will help attract men back to the land, and then, with the motor truck, help them market their products with less intervention by profit-taking middlemen.

The trunk roads from the great cities to the smaller towns, the subsidiaries leading from them through the more rural regions—all these will be united in great systems that will provide through and uninterrupted passage from any place in the country to every other place.

Mr. Breed. Guiding this work of co-ordination, there will be, in Washington, a National Highway Commission, second in importance only to the Cabinet Departments. Beyond the proposed Lincoln Highway, that Commission will have under construction, or completed, before 1925 at least four other transcontinental highways, planned solely from the standpoint of highway economy, without reference to existing cities and towns. Given the roads, the population will settle along them, just as it has along the railroads. Throughout history civilization has always followed the lines of communication. At first, Nature determined these lines; now they are determined by Man.

Meanwhile, each State has been perfecting its own system within its borders, building through routes between its important points, with whatever spurs are necessary to connect with the National system and with similar routes in adjacent States; and the counties have helped, with feeders to these routes from every remote village and hamlet, until all are sharing to the fullest extent in the surge of national life.

With such development for the highways, with the suggested improvement of the waterways, and the hoped for resurrection of the railways, the transportation facilities of this country 5 years hence ought to be more than adequate to meet the demands on them.

So much for the vision—akin to what every one probably holds for his own special line—now for the toil to make it real.

First of all, in every line of engineering, one must work for greater permanence in result. Europe has proclaimed that lesson, but this country has not heeded it. With the vigorous impatience of youth, stability has been sacrificed to speed, size has been acclaimed rather than soundness.

The public must be roused to demand that engineers build deep and well. They must learn to spurn the shoddy, beloved of their politicians. Last week a delegation from an up-State county came importunate to the Commissioner's office in Albany. "Gentlemen," he said, "I want you to have these roads, but I have exactly $300 000 to spend in your county. Would you rather have 10 miles of good road that will last you 15 years without ever having to be closed for repairs; or 20 miles of poor road that may last for 3 years and will have to be closed often?" With one accord they cried, "Give us the 20 miles."

At the speaker's remonstrance, one member of the delegation said, pityingly: "The counties want the roads. The cheaper they are, the more we get for our money in them. The State has to do the maintaining, and most of the State's taxes are paid by New York City. What is our worry about permanence?"

It is a worry, however, that engineers cannot dodge. The National routes should have foundations at least comparable with the best railroad practice, and be surfaced with one of the permanent types—the choice depending on the materials most available in a given locality.

The State routes should have the same surfacing and strength of foundation. Within a 30-mile radius of the large cities, the foundations must be still further deepened and the pavement widened to sustain the heavier traffic. The county roads should have a semi-durable surfacing, according to the need shown by a traffic census, and a proportionately good foundation, except within 20 miles of the larger towns, where they should again be of permanent type. Mr. Breed.

So much for the basis of permanence. There are many other factors in a roadway, however, besides foundation and surfacing. They come under the heading of "details", through closer attention to which, engineers, in every line, may find opportunity for much improvement. A few may be mentioned which are of fundamental importance in highway work, and yet have hitherto received rather cavalier treatment.

Width of Roads.—The least width for National roads and most of the State routes will be 20 ft. for the pavement proper, with an additional 5 ft. or more for the shoulder; that is, where traffic density requires only two tracks; for each additional line of traffic, there should be an additional 9 ft. of pavement. On a few State roads, where traffic is lighter, and most of the county roads, there will be a 10-ft. pavement of hard surfacing and beside it 10 ft. more of earth road which may be improved when necessary to make the full two-line traffic pavement.

Alignment and Grades.—Although the straight line shortens the distance, curves are often necessary in order to conform to the broken topography of the country. This matter of alignment and grade will receive more careful study in relation to economizing the fuel used in the propulsion of motor vehicles. All curves should be reduced so as to afford a sight distance of 600 ft. Where that is impossible, the curves may be split by a parking place or posts in the center so as to divide the traffic. Buildings will be removed from dangerous corners, and banks graded back; and, wherever possible, curves will be widened so as to secure greater safety for passing vehicles.

Drainage.—No matter how well a road has been drained, its use generally shows that more drainage is necessary. Ditches must be widened as foundations are deepened. Only by keeping the subsoil dry can it act as part of the foundation, cheapen the cost of the pavement, and insure coherence of crust during wet subsoil conditions. The speaker foresees the return of the deep ditch far enough away from the roadway proper not to imperil the traveling public, and providing run-offs and lateral systems to drain away the sub-surface water.

Marking of Routes.—Is it Utopian to hope to have, at every turn, adequate sign-posts which one can read when going at a speed of 10 miles an hour? There is no doubt that there will be general acceptance of the banding of poles in different color schemes to indicate main

Mr. Breed. traveled routes, so helpful has this procedure proved in New York and the New England States.

Esthetic Features.—An ugly sign-post is a public offense, so is the billboard and the unnecessary danger sign. They will not be tolerated. On the other hand, the furtherance of the Arbor Day and patriotic memorial idea will enhance the beauty of the roadways with shade trees and shrubs, and parking spaces must be provided at definite intervals, and also the sorely needed rest and comfort stations. A greater length of culvert and the general use of the straight line in its design will obviate the need of unsightly guard-rails around its ends. The use of boulders and rustic guard-rails will be an improvement over the ugly painted wooded affairs now used, and they will also be cheaper.

Letting of Contracts.—Because of the greater quantity of work to be done and the scanty number of contractors to do it, there is need for encouraging large construction organizations to enter the highway field. This will mean ultimate economy. A large number of contracts will be let in lengths of from 15 to 30 miles, justifying the use of special equipment and special labor-saving devices, such as the short contracts cannot warrant, because of the disproportionate overhead charge. The most adequate equipment is necessary to-day to supplant the rapidly diminishing quantity of hand labor.

Maintenance of Traffic.—Many of the old roads will have to be reconstructed in order that they may take their place in the new systems. Experience in New York State has shown that where a semi-durable pavement has broken up because the weakness of a soft and yielding subsoil has been accentuated by heavy traffic during the spring thaws, it has been cheaper in most cases to fill the broken gaps with a rigid type of pavement—of concrete or with a concrete base—rather than go to the expense of deeper excavation for extra drainage and for extra thickness of sub-base foundation under the old type. These gaps then become a permanent start toward the reconstruction of the whole road.

In building pavements of the widths proposed, it will be possible to build one longitudinal half at a time, and thus provide for a long-suffering public that has been discommoded with insufficient detours.

Thus, are suggested some of the possible developments of the next 5 years. Their practicability to each engineer depends on his experience, viewpoint, and temperament. They may not prove practical at all. Then they must be modified or changed. That is of less concern. What greatly matters is, to be free from too close dependence on the past, to see the future with larger vision, to apply permanence as the one standard of success, and to give to details the devoted attention of artists and scientists. These traits, sought in common, will

strengthen the alliance among us all, and, to these traits, the speaker believes, will be due the greatest good that may come from the highways of the future. Mr. Breed.

In reply to the inquiry as to the comparative merits of tar and asphalt in surfacing, the speaker finds it difficult to generalize. There are certain kinds of stone in New York State, such as gneiss, from which the best results have been obtained with tar. There are other rocks, like trap, from which the best results are secured with asphalt.

This can probably be explained better by saying that tar has a tendency to go down through the rock. The gneiss rocks are more friable, and hold the tar up better, but with them asphalt has a tendency to work up or bleed—this is a condition which probably all know—if it has not thoroughly penetrated. With the harder rocks, it is found that asphalt gives the best surface, because it penetrates the interstices.

The tendency of tar to go down often makes it necessary to surface treat the road with cold tar and fine stone, sand, or gravel. If this is not done, the surface will soon become toothy and pitted.

EUGENE W. STERN,* M. AM. SOC. C. E.—The preceding speakers have not exaggerated in the least the importance of the highway problem in the United States. It is a very live subject, and one that demands the fullest discussion and propaganda for enlightenment. Mr. Stern.

It is hoped that this Society will take a much more active part in the propagation of information on this matter than it has in the past, and that it will encourage, in every way, meetings for the discussion of all matters pertaining thereto.

In America, with few exceptions, road problems have not been attacked with proper vision and boldness. Macadam roads have been built, when hard paved surfaces should have been laid. Paved surfaces have been too narrow, curves have not been easy enough, grades have been too steep. Drainage has been neglected, shoulders have been neglected, and, most important of all, proper upkeep has been neglected.

There have not been generally adopted proper regulations limiting the size, wheel loads, etc., of vehicles. Organization and administration of highway bureaus have been niggardly, poor, inefficient, and utterly behind the times. There has been lack of comprehensive plans, and of co-ordination in linking up highway routes; and, lastly, there has been too much politics in the entire highway problem. The foregoing deficiencies are causing the loss of many millions of dollars annually to the taxpayers, and they are all easily preventable.

Some experiences on road work in France, where the writer served for more than a year with the A. E. F., may be of interest.

* New York City.

Mr. Stern. The administration and organization of the French road bureau is under civil service rules, and is efficient and excellent to the highest degree. Politics does not enter into it. All road officers are trained engineers, graduates of the Ecole Polytechnique and of the Ponts et Chaussées, and are retired at the age of 62 on a pension.

The organization for maintenance and repair is very thorough, and is admittedly the best in existence. Men called *cantonniers* are stationed along important roads at distances of from 3 to 6 km., living in little houses along the roads. They are at work continually, and never allow the roads to get in poor condition. Even if there is wear, the repairs are so skillful that the surface wears down smoothly.

British road officers have told the speaker that the roads in France are maintained at much less expense than in Great Britain, owing to the better organization.

Even in war times, it was surprising to see how well their organization functioned, though, of course, it was impossible to do the work as well as in peace times, as men and materials were often not available. Women and old men maintained the roads, back of the zone of operation of the armies.

French roads are thoroughly drained, every precaution being taken to carry away the water, and keep the sub-base dry. All roads have side ditches, and the National roads likewise have gutters, draining into the side ditches. The ditches and gutters are kept scrupulously clean, the grass being close-cropped, and the bottoms kept smooth. The water in the ditches is always kept flowing.

Shoulders are grassed, and trees are planted on both sides, and serve a double purpose, absorbing the excess moisture from the shoulders, thus tending to prevent frost heave, and, of course, the trees add very much to the beauty of the road.

Nearly all French roads are water-bound macadam, the important roads having a Telford base, only a small percentage being paved with granite, or treated with tar. They are wonderfully well built, the greatest care being taken in every detail of their construction. The macadam surface is made with one-size stone, 2¼ to 2½-in. trap or granite, most thoroughly consolidated with a heavy roller, usually weighing 17 tons, the stone being kept thoroughly wetted during the process of rolling. The roller passes over the surface from 150 to 175 times, and, when the job is done, the surface is so thoroughly consolidated, and the stones so interlocked, that it looks like concrete. Regardless of the great excellence which the French have attained in the building of macadam roads, however—probably the very best of their kind in existence—the war proved beyond any question that they are not suited for motor vehicle traffic. Shortly after the motor trucks of the U. S. Army commenced to use these roads extensively, they wore out rapidly, becoming full of holes and ruts. It required a

great deal of labor and huge quantities of stone to keep them at all serviceable. Mr. Stern.

If there had been hard paved surfaces on the main highways in France during the war, millions of dollars would have been saved, and a great burden on the railways and canals would have been avoided, as about 40 000 tons of road stone had to be transported daily for the use of the armies on the Western front alone.

In France, before the war, few motor trucks were used, and these mostly in the cities, or for a short distance outside. When war came, this situation changed almost over night. Every available motor vehicle was requisitioned, and the traffic developed by leaps and bounds. The motor truck saved France.

The French road engineers, although capable men, and not lacking in vision, had an entirely new problem to meet, but they could not improve the road surfaces in war time. It was too late. They were compelled to use macadam for all repair and new construction, and now they are frank in admitting that it will not meet the necessities of the future. The upkeep costs far too much.

In the United States, the great question today is—"How can we best meet the road problem?" The speaker believes that it can be solved as readily and efficiently as other engineering problems, if it is attacked in the right way.

First.—Road building must be taken out of politics, and put in the hands of capable men. Highway commissioners should be able engineers, of thorough training in road work, who possess vision and force of character, combined with administrative and executive ability of a high order. It has been only too common for highway commissioners to be politicians, lawyers, or of any class not meeting the above requirements.

Second.—The remuneration and conditions surrounding the service should be made sufficiently attractive to induce professional engineers of a high grade to follow this calling. An engineer in responsible charge of road planning and construction should have certain qualifications. Besides technical knowledge, he must have vision—imagination for the future—balanced by good judgment. If he does not have this, and the courage of his convictions, he is in a position to waste huge sums of the taxpayers' money. His decision alone, as to what type of wearing surface should be used, may mean great saving or loss to the community.

There is an example of this in New York, and in many other States, where macadam roads have been built in recent years, when every indication pointed to the lesson that surfaces of this type would not stand the growing motor vehicle traffic. The result is that there are many thousands of miles of macadam roads costing annually for upkeep alone more than $1 000 a mile, whereas, had a road of proper

Mr. Stern. type been built, the annual gross cost to the taxpayers would have been almost cut in half. By annual gross cost, the speaker, of course, means interest on the cost of construction, plus amortization, plus annual upkeep.

The speaker has only touched on the more important considerations in the solution of the road problem, as he believes these to be fundamental. Given proper organization and leadership, the rest will follow.

Mr. Tomkins. CALVIN TOMKINS,* ASSOC. AM. SOC. C. E.—The speaker calls attention to two or three points which have impressed him in the discussion of this interesting subject. On the New York side the highway system is completed, and also beyond the meadows district in New Jersey, where there is an excellent system radiating from the Passaic River; but, in the intermediate meadows district, there is lacking any kind of road system, or any plan, so far as the speaker knows. There are three principal roads crossing the meadows, and no adequate transverse roads running north and south between them, as there should be. Before industrial development proceeds to any great extent in this territory, a general plan of road construction should be adopted, in anticipation of the needs; otherwise, it will be necessary, in the future, to go to very great expense in order to provide a suitable system. The roads should converge on the meadows as much as possible at a few crossings on the Hackensack and Passaic Rivers, so as not to interfere with the river traffic any more than can be helped. This interference of water and land traffic has already become a serious problem.

The speaker doubts the advisability of building a bridge over Newark Bay, as the latter is second in importance only to New York Bay, as a part of the Harbor of New York. In its present condition it is a shallow body of water, and of little use; but it can be dredged, and at far less expense than that incurred at Bremerhaven, Glasgow, or Hamburg, and made a most important adjunct to the harbor. Bridges across it will interfere seriously with its navigability.

The speaker believes the time has come when a system of tunnels under the Hudson should be planned in advance. These first vehicular tunnels are only the precursors of many which will be built, and the lay-out of the system should be such as to prevent interference. The conditions in the bed of the river are known, and it is of the greatest importance to leave those conditions so that many tunnels can be constructed. The speaker has been informed that there is in existence a plan for an Erie Railroad river tunnel, running diagonally across the river, which, if built, would interfere seriously with future east and west tunnels.

* New York City.

Mr. Thompson's remark relative to the utilization of small unprofitable railroad feeder lines for highway uses is important. Highways have demonstrated their efficiency as feeders for the railroads. The small railroad lines are not economical, and, just as trolley construction has been stopped by the building of good roads, so feeder railroad lines will be stopped, and many of them can be used advantageously as highways. Mr. Tomkins.

However important vehicular tunnels may be for communication between New York City and New Jersey, one should not lose sight of the fact that the fundamental needs are railroad tunnels. They are needed as soon as they can be built, and a strike would be a fortunate rather than an unfortunate occurrence for New York City if it helped to demonstrate the absolute necessity of establishing physical all-rail connections with the great continent to the west.

The newspapers state that only 20% of the population of Petrograd remains. The rest have been starved out because of the desperate consequences of the interruption of railroad traffic. The same causes may eventually produce like results in New York City unless continuous railroad service can be maintained with the continent. At present, there is only the intermittent railroad lighterage car-float services across the harbor, and the traffic will be interfered with continually by labor disturbances, because the harbor transfer is the weak link in the system, and will be the point of attack every time a railroad dispute arises.

H. F. Dunham,* M. Am. Soc. C. E. (by letter).—The discussion on American Highways is full of interest and encouragement. The encouragement is obvious, and was to be expected, because many conditions are somewhat novel and, therefore, the pendulum is liable to pass the ordinary limit. When this occurs, it is natural to accelerate further instead of imposing restraint. It is more common and popular in any event. Mr. Dunham.

A few lessons from the past should be cited and heeded. When it was shown conclusively that electric traction offered certain advantages in certain localities, scant regard was given to the fundamental rights of existing lines of steam transportation, or to the true interests of the general public. In that period of enthusiasm, it was held in some States that to permit an electric line to carry freight would be to treat unfairly a long established steam road in the same vicinity, and such permission was denied, not in a particular case, but in all cases. Thus, many electric lines that might have been valuable feeders to the steam roads and of great value in their districts were discouraged and not built. At the same time, steam roads between cities that had been almost created by those roads, were linked up, with little or no objec-

* New York City.

Mr. Dunham.

tion, by electric lines that are now in need of more passengers, higher fares, or new investors. The errors in the two methods thus presented, opposed alike to good morals and good legislation, have helped to impoverish the public, weaken all service, and introduce chronic troubles.

These are facts that should be examined and studied well before entering on an almost identical course following another change or advantage in the application of mechanical power. Had a different course been followed, and electric lines located and given rights where the best interests of all concerned demanded, the two systems might be working in harmony in many places throughout the country where serious difficulties now exist; and, further, a close approach to that more satisfactory condition could have been reached, if the demands of promoters had been limited by competent railway boards or public service commissions.

After this broad object lesson, and in the midst of further activities, the United States Government will not set aside funds to be used in the improvement of a highway unless that highway is now "a post road", while it is notorious that post roads, especially in New England, were located over summits nearly as high as could be found. At the present time, and for this reason, improvements are made following bad locations and the most difficult grades. First, there should be better co-operation between Federal, State, county, and municipal authorities. Labor interests should be included, but it may be questioned whether wrong labor activities, that is, wrongly or badly planned, should lead to extended new construction, even if such new departures would require the employment of many workers. Recently, we have seen that mere numbers are not an effective safeguard against injury to all classes. Parts of the United States and provinces in Canada and Russia show this. Where a weak link exists because of active corrosion, it is better to safeguard the weak place than to add elsewhere to surfaces that must be exposed to the same acid influence. Engineering would soon be a synonym for impoverishment if wrong deeds always insured new and extended construction. One may question and doubt whether engineers should encourage larger factors of safety, because of political unrest among American workmen.

In electric road construction, it was generally intended that the cost of right of way, construction, and equipment should be covered by bond issues. The stock became valuable from earnings in excess of interest and operation charges. Profits increased as maintenance, equipment, and depreciation were neglected. Often the roads were left in the possession of the bondholders to be operated or abandoned. All this was individual or business enterprise, where bad judgment, want of foresight, or too great enthusiasm brought discomfort.

Mr. Dunham.

Now, however, in the new adventure, where the rights of way and the roadbed are owned by the public and, of necessity, kept in some kind of condition by that public, complications are increased immensely. The Ford automobile and the heavy truck have practically equal rights. The light rig and the locomotive are on the same roadbed without rails, and both look to the public for support and safety. A requirement of one is that no special diversion of rainfall shall occur at intervals on high grades. An evil of the other is a groove in the roadbed that becomes a destructive river in every hard storm. The public makes repairs. Where the ground is soft, the heavy truck depresses the roadbed. The public brings the surface up to grade. Deep freezing and thawing make radical changes in the surface. The public attends to that. In winter, drifting snows bury fences and fill up the cuts. The public opens the way without the aid of a snow plow.

It seems worthy of remark that in a discussion on highways in a State the latitude of which is 42°, and where the snowfall is exceptional, not a word was said bearing on snow blockades or the expense of keeping a bridle path open in weather that closes up the Hudson River. The only reason for this must have been the confidence engineers share in the assistance to be derived from the public. We know what has been done under the stress of war, when long trains of trucks were brought through deep drifts in the mountains. We seem to think a similar service can be maintained at public expense.

In reaching out, however, into districts not occupied by railroads, it should be remembered that throughout a large part of the United States winter service must be abandoned above the snow line, and for no small part of the year the equipment is idle. To that extent this method of transportation suffers in comparison with railroads.

On steam roads in this country, freight is now moved at an average cost of not far from 2 cts. per ton-mile, and it is on such figures that determinations of profit and loss are made. Back of the actual rate, whatever it may be, there are years of operation with accounts that disclose almost every item of expense. How much is accurately known of the cost of hauling by motor truck per ton-mile over roadways provided and kept in repair by the public? Repairs to the trucks at this date are usually made by the owners.

In Massachusetts, steam road and highway automobile accidents are not returned under exactly similar headings. The Commission gives the number of passengers killed and a detailed account of accidents to employees on steam roads. It is not difficult, however, to determine how many employees are killed by trains in motion, and, in this way, to make fairly accurate comparison with the record of "Occupants of Automobiles."

Mr. Dunham.

Thus, in 1918, in that State, 33 persons (13 passengers and 20 employees) were killed on steam roads. Of occupants of automobiles 136 were killed. The totals for the year may be thought to be more surprising: Steam roads, killed 247 (including 98 trespassers, not on grade crossings), injured, 137; killed by automobiles, including motorcycles and motor trucks, 499, injured, 8 598. These figures show a phase in transportation which cannot be disregarded in highway discussion and should be remembered when it is sought to change a steam road branch to a highway.

These losses in life, time, crippled limbs, and cost of recovery may not be classified in any particular schedule, but they are very real and are losses on the community balance sheet in any final auditing, which are and always will be on the wrong side.

Mr. Woolley.

WILLIAM E. WOOLLEY,* ASSOC. M. AM. SOC. C. E. (by letter).—This discussion on highways is very interesting, and several of Mr. Breed's remarks might apply very aptly to English conditions. Many English highways which formerly were suitable for ordinary traffic, have proved to be totally inadequate when subjected to modern traffic conditions, with its heavy motor lorries, etc., owing to their non-rigid foundations and to the unsuitable material used for their surfaces. This has been most marked during the war, when fleets of heavy military motor lorries were in constant use, and at a time, too, when there was little available material and labor for repairs and a road-stone control besides.

Often in the past, the cheapest stone in the district was made use of because of its cheapness. This, in many cases, did not entail the use of durable and tough qualities of metaling. There has also been a marked absence of foundations suitable for carrying modern weighty vehicles.

In order to stand modern traffic conditions in towns, care, of course, must be taken that a thoroughly firm and solid foundation of sufficient thickness is provided, a suitable material being concrete which is being much advocated in England at the present time. The surface should be of durable material suitable for the particular kind of traffic to which the road is subjected. The road should be constructed on the most permanent and soundest principles. It has been established that ordinary macadam roads are not suitable for withstanding the heavy modern traffic in big towns. Weak, non-rigid foundations are often denoted by sinkage in the center and rising at the sides.

In regard to English roads, it is noteworthy that, having in a great degree been neglected during the war period, many are now in such a bad condition that the authorities are reconstructing them. Several of the main London roads are at present being dealt with in this

* London, England.

manner, and the writer knows of several county roads undergoing similar treatment, a stretch of one-half, longitudinally, being finished at a time, so as not to close the road to traffic. Mr. Woolley.

It is reported that the British Government, through the Road Board and the County Councils, is to assist the authorities in carrying out road works, by making grants amounting in the aggregate to about £10 000 000.

Paper No. 1437

THE EAST CANYON CREEK DAM*

By A. F. Parker, M. Am. Soc. C. E.

With Discussion by Messrs. Edward Godfrey, Samuel Fortier, A. J. Wiley, Herbert E. Bellamy, and A. F. Parker.

Synopsis.

This paper describes the design and construction of a concrete dam which depends on its arched form for stability.

The East Canyon Creek Dam, on East Canyon Creek, Morgan County, Utah, is 12 miles above the Town of Morgan and 37 miles from Ogden, Utah. The reservoir formed by the dam stores water for late irrigation of lands in the Salt Lake Valley south of Ogden, and forms a part of the irrigation system owned by the Davis and Weber Counties Canal Company, of Ogden. The mean altitude of the site is 6 000 ft.

The structure is of interest because of its slight appearance and the successful manner in which it stands the test of use. The arch has a length of 128 ft., the radius of its up-stream face varying from 78 to 98.8 ft. The arched portion is 190 ft. high above bed-rock and 145 ft. above the outlet; its thickness is 26 ft. at the bottom and 5 ft. at the top. The arch abuts against a tangent of gravity section on one end, and against a tangent structure of hollow-deck type on the other. The outlet gates are of the full balanced type.

The dam was built during the winter, and the materials available for sand were of very doubtful appearance, containing much fine silt and

* Presented at the meeting of May 7th, 1919.

clay. The success of the structure adds to the number of arch dams built which demonstrate and sustain the use of the simple formula for the strength of cylinders in computing the dimensions of such dams. The costs of the work are given.

General.

In 1896 a dam was built on East Canyon Creek, 58 ft. in height above the outlet; in 1900 the height was increased by an addition of 30 ft., and in 1902 it was raised to its ultimate elevation of 100 ft. The first dam formed a reservoir having a capacity of 3 850 acre-ft., and this was increased by the additions to 9 000 and 14 000 acre-ft., respectively.

The old dam was of the rock-fill type, with a steel core. With conditions as they existed at the time this dam was built it is probable that this was the best type to be adopted. It served its purpose for a long time, but finally developed a leakage which ultimately amounted to about 40 sec-ft. There seemed to be no danger of a break in the dam, but the leak became so great that it threatened its usefulness for storing water. The impossibility of repairing the leak and the need for a greater storage capacity caused the building of a new structure at the lower or down-stream toe of the old dam.

Preliminary surveys were made in 1912. The design and plans of the dam were under discussion for two years, and the contract for construction was let on April 21st, 1915. The dam was completed in June, 1916. Building roads, making plant foundation excavations, and sundry preparations consumed much time, and the first concrete was placed on September 30th, 1915. This resulted in practically all the concrete work being done in the coldest winter weather and under very trying conditions generally.

Water Supply.

The water-shed has an area of 156 sq. miles and is high, mountainous country, with an elevation of from 6 000 to 9 000 ft. The portion of the stream flow available for storage is that of the winter and the spring floods. The quantity varies greatly, according to the precipitation of the seasons. As nearly as could be determined, there was probably as much as 65 000 acre-ft. available in flush years, with a probable minimum of 20 000 acre-ft. when precipitation was light. The econo-

mical capacity of the reservoir was fixed as 28 000 acre-ft., which called for storage to the 140-ft. contour above the outlet to the old dam.

Features of the Site.

At the site of the dam a strong, prominent upheaval of conglomerate rock shows above the mountain slopes for several miles. Where the creek cuts through the conglomerate, a short, deep gorge or canyon, with solid rock walls, makes a favorable place for building a dam. The rock canyon is only about 1 500 ft. long, with the up-stream end sharply defined by vertical cliffs, and the lower end gradually tapering off to the general mountain slopes.

The rock is a limestone conglomerate, formed of fragments of rhyolite, sandstone, and limestone cemented together with calcite. The rock lies in beds of greatly varying thickness; the bedding planes are very strongly marked, and have a heavy down-stream dip. There are many soft and disintegrating spots; and some of the bedding planes have thick fillings of rotten rock and clay. Between some of the bedding planes slight stratification shows in the thinner layers, but where the planes are widely separated (sometimes as much as 40 ft.) there are massive layers of conglomerate with no stratification, and they are exceedingly firm and hard.

The sides of the canyon are very irregular, but, in general, are roughly vertical—in places overhanging—for the first 40 to 60 ft., and, above the vertical cliffs, the slopes fall back at varying angles. A casual inspection gives one the impression that the rock is unreliable, both as to strength and water-tightness. A close inspection shows the possibility of finding good sound rock on which to found a dam.

The conformation and quality of the rock fixed the location of the dam at the down-stream toe of the old dam. The body of the old dam precluded the adoption of the best location. It became necessary to locate the dam lower down stream, and even then the excavation cut the toe of the old dam somewhat. It is evident that extending the excavation into the toe of the old dam was a matter of difficulty and grave risk. The fact that the reservoir above the old dam was full of water and that a leak of 40 sec-ft. existed added to the difficulty and danger. That the work was done successfully is due to the absence of alluvial material. The excavated material was nowhere finer than coarse sand, but most of it consisted of coarse fragments, with many large rocks.

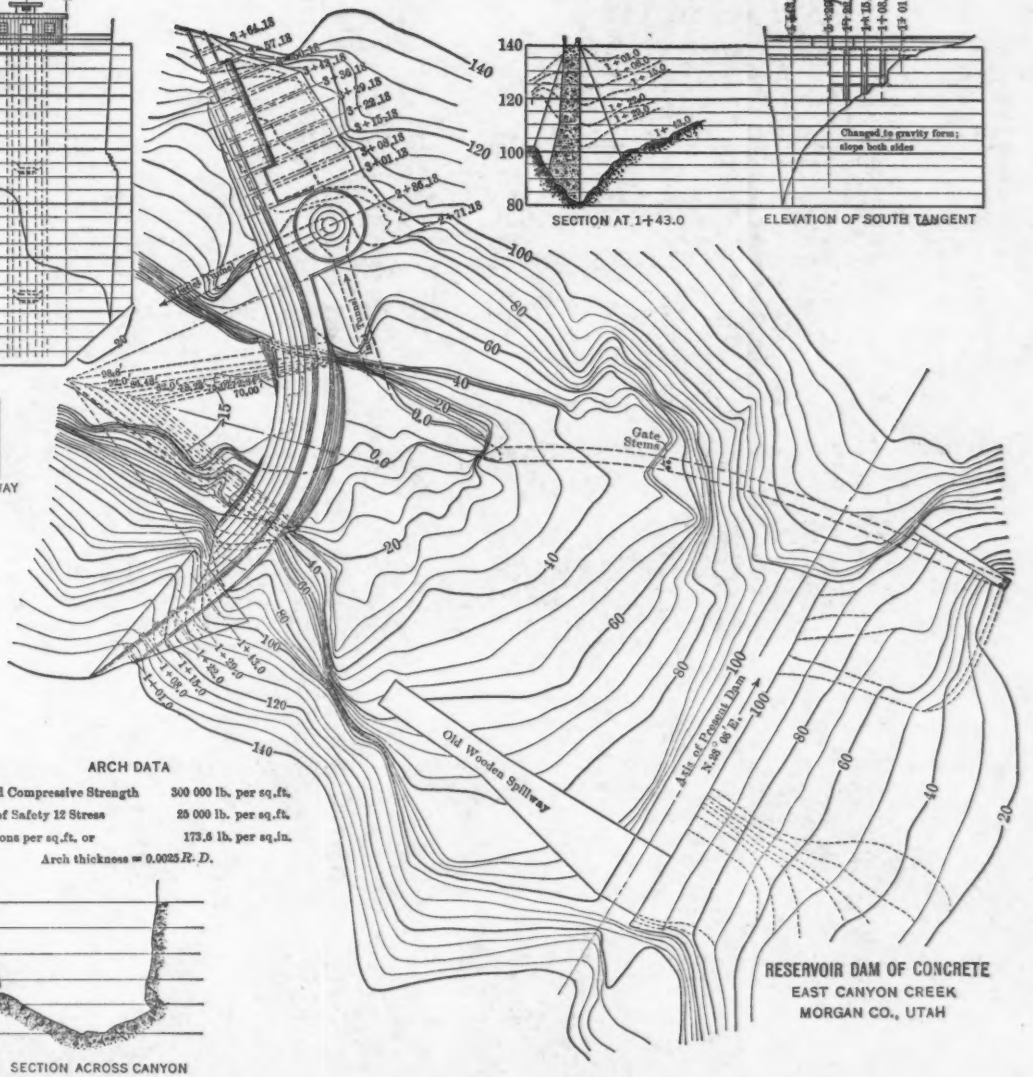
SECTION ACROSS CANYON



RESERVOIR DAM OF CONCRETE
EAST CANYON CREEK
MORGAN CO., UTAH

Bed-rock was found 45 ft. below the creek bed, where the average distance between the canyon walls was 45 ft. The surface of the bed-rock was very irregular, being cut with channels and pot-holes, but all smooth and highly polished, evidently by flowing water carrying sand and drift. Some of the pot-holes were as deep as 5 ft., and much larger at the bottom than at the top; and remains of the boulders that ground them out were found in each. No cracks or fissures were found, and the only preparation necessary to make a foundation was some roughening of the polished surface.

The Design.

The peculiarities of the site plainly indicated the adoption of a dam of the arch type. The location, above several towns and a railroad, where a break would result in a disaster of magnitude, made safety of prime importance. Calculations showed that an arch dam could be built for about one-half the cost of any other type. It was realized that the slight appearance of an arch dam of short radius, as compared with the greater bulk of gravity sections, might cause apprehension as to safety. It is probably this slight appearance that makes so many engineers reluctant to adopt the pure arch type.

From the numerous articles describing arch dams, the many discussions on their design, and the frequency with which lists of arches actually built appear in such articles, one gains the impression that a general doubt exists as to the safety of structures of such slight appearance. However, the fact that so many arch dams—many of strikingly light section and frequently subjected to trying conditions—have been built without a single instance of failure occurring, which cannot be said of any other type, is strong proof of good qualities and safety. The test of actual use shows that arches under water pressure are the safest form that can be built.

All that could be found in print relating to arch dams was studied, and the proposed mathematical treatment was applied to the design of the structure. It was found that in all cases the dimensions necessary to resist the complicated shears, bending, and temperature stresses did not exceed the dimensions computed from the simple formula for the strength of cylinders under pressure, when the unit stress on the masonry was conservative. To decide on a conservative unit stress, one must be guided by the quality of the materials, the importance of the

structure, etc. Examples are found of arch dams in successful use having stresses ranging from a minimum of 10 tons to a maximum of 61 tons per sq. ft. On account of the importance of the structure, in this case, a stress of 12.5 tons per sq. ft. was adopted.

The thickness of the arch was found by using the simple formula,

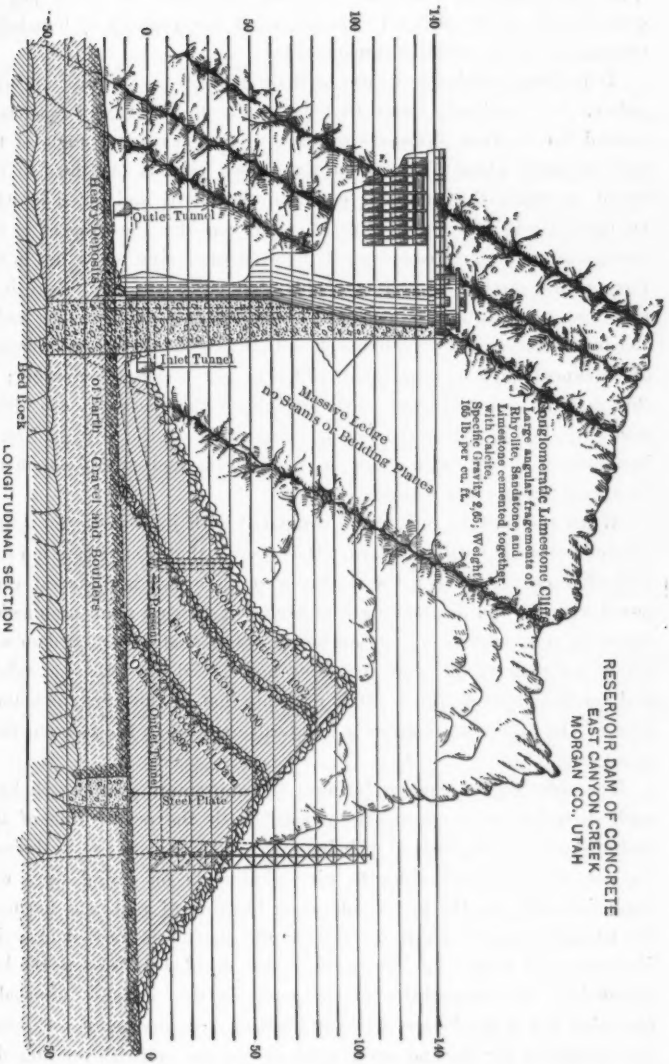
$$T = \frac{RP}{S},$$

where T = the thickness of the arch, in feet;
R = the radius of the up-stream side, in feet;
P = the water pressure, in tons per square foot;
S = the stress on the masonry, in tons per square foot.

For practical use, let the depth of water at any point be represented by D; it is easily found that $0.0025RD$ gives the thickness for a stress of 12.5 tons per sq. ft. The thickness of the arch, in this case, was finally determined by the use of this extremely simple formula.

In the hydrostatic arch, the loading is definite and symmetrically applied, as well as easily determined. The stress is primarily all compression, increasing directly as the depth of the water. Ice thrust, when present, adds a very uncertain amount of compression, and this is best provided against by the use of vertical reinforcement to distribute the stress over a larger area; but the elasticity of the masonry and the supporting rock, the changes due to variations of temperature, the combination of cantilever and gravity action, etc., necessarily produce complicated shear and bending stresses; of such stresses but little is really known, for their determination involves assumptions on which authorities do not agree, and which, in the final analysis, are only the judgments of the designers.

It is to be regretted that there is no way of determining the actual factor of safety in arched dams. All that is now possible is to apply the formulas of theory and build the structure; if it does not fail or develop signs of weakness, the calculations used in the design may be pronounced safe and proper to use in similar cases. Until some arch dam actually fails under pressure, there is nothing to show the true limit between bold and conservative design. In examining published plans of existing gravity dams, does it not sometimes become apparent that, in some instances, the higher central and so most costly part could have been made in the form of an arch with tangent ends of gravity or other



LONGITUDINAL SECTION

FIG. 1.

type, according to conditions, without detriment to safety and at considerable saving of cost? The saving in the quantity of foundation excavation alone would be considerable.

It is always desirable to use as little concrete as is consistent with safety. It is variously stated that the minimum quantity of concrete is needed for a given thickness of dam when the central angle of the arch includes about 133°, when the versed sine is one-third of the chord, or when the radius is equal to the chord multiplied by 0.54. In this case it was found impractical to consider the element of the minimum quantity of concrete; it involved producing overhangs in the faces of the arch, and it is probable that cases are rare where it is practical to maintain a constant angle between the limiting radii. Recorded examples of arch dams show that in some cases local increases of thickness have been made in order to give increased strength; in this case no such additions to the calculated thickness was considered necessary, but in places the joining of the arch to the cliffs had small increases of thickness in order to cover cracks and soft places in the rock, and for no other reason.

When the arch is very thick, compared with its length, the matter of arch action is very uncertain. It is known that a structure loses its arch characteristics when the thickness at the crown is too great, compared with the radius and length of arch, but at what point arch action ceases is very uncertain; one authority states that a curved dam will act as an arch if the thickness does not exceed one-half the radius, and another says one-third. It is probable that in this case the bottom part of the arch acts more as a bulkhead or plug to the canyon, than as an arch.

The sides of the canyon forming the abutments of the arch have such direction as to be nearly parallel with the center line of the included arch angle, instead of being on radial lines, as is to be desired. To cut into the rock sides to give abutments on radial lines was expensive, and, on the north side, such blasting of rock was too near the tunnels and gate-shaft for safety; the shaft was located close in, for reasons of economy. Therefore, it was decided to trust to the key afforded by the inequalities of the rock—in this instance unusually favorable for a good key—without blasting out any more rock than was necessary for finding good solid abutments, notwithstanding the fact that the line of the rock made an angle with the line of the

resultant of the arch thrust equal to the full angle of repose for masonry. There was placed over such abutments steel dowel pins, of 1-in. square twisted pieces, 4 ft. long, placed one-half in the rock, in grouted holes, and the remainder built into the concrete, one dowel to every 3 ft. vertically and horizontally. Such dowels may not do much good, but they certainly give a look of security.

To fit the arch to the cliffs properly, it was found necessary not only to adopt radii varying in length from 70 to 98.8 ft., but, at Elevation 60, to change the batter from the up-stream to the down-stream side. The batter begins on the up-stream side of the dam at 10 ft. below the level of the old outlet, assumed for convenience as Elevation 0.0, so that the point 10 ft. below has a minus value. The down-stream side is vertical to Elevation 60, where the batter changes to that side, and is continued thence to the top. The calculations for thickness bring the dam section to a point at the top; but the top thickness is assumed in this instance at 5 ft., and the surface batters downward to meet the other batter at Elevation 110, where the thickness is 7.41 ft. More for appearance than anything else, there is a rib at the top, on the down-stream side, of 8-in. projection and 4 ft. deep. On the up-stream side there is a parapet wall, 3.5 ft. high, and opposite is a railing of 1½-in. pipe supported by posts of 3-in. I-beams; provision is made for the expansion and contraction of the pipe.

The length of the dam over all is 273 ft., the south tangent being 43 ft., the arch 128 ft., and the north tangent 102 ft. Up to about Elevation 60 the arch is not more than 65 ft. long, mostly only from 45 to 50 ft. The excavation for bed-rock extended to 45 ft. below the creek bed, or 50 ft. below the old outlet, which was assumed as the zero of elevations. The total height of the dam is 190 ft. From bed-rock to Elevation — 10 the thickness is constant, because of balanced pressures; the use of forms began at Elevation — 10, with a dam thickness of 26.25 ft., but to that level the thickness is from 28 to 30 ft., for in the foundation timbering only the heavy timbers were removed, and the whole space between the lagging was filled with concrete.

The length and radius of the arch was determined by the set of the tangent ends. It was necessary to use tangent ends, for the calculations showed that otherwise a longer radius was needed, and then the ends of the arch would be too nearly parallel with the sides of the canyon; in fact, the dimensions and form adopted showed that the

cost of building would be less than with any other form tried. The most difficult matter involved in the design was to find a balance of the elements involved, at the same time having due regard for economy and sound rock for abutments. This was only accomplished by patience and many trials of different forms and locations.

The Tangent Ends.

The south tangent of gravity section was first designed as a deck section, but after the foundation to receive it was blasted out, the contour was changed so much that the gravity section with slopes on both sides was substituted. On the north side the rock fell away in such a manner that a proper gravity section could not be built on it where the slope of the structure is down stream, and it became necessary to adopt a hollow-deck section where the sloping side could be up stream. The deck is formed of arches below and a straight surface above, set on piers 7 ft. from center to center. The foundations of the tangents, perched on the sides of the cliffs, had dowel pins of the same kind as those used in the arch abutments; there were plenty of them, and they were set into the rock before the concrete was placed.

As it was necessary for the tangent ends to receive the thrust of the arch and carry it to the rock sides of the canyon, the hollow spaces in the north tangent required special treatment. Accordingly, two heavy braces or ribs were placed, reaching from pier to pier and to the side of the canyon. The lower brace, at Elevation 115, is 7 ft. wide and 4 ft. high, with a reinforcement of 36 rods of 1-in. square twisted steel; the upper one, at Elevation 122, is 6.25 ft. wide and 3 ft. high, with 20 rods of the same size and kind; the horizontal rods in both beams are surrounded with hoops of ½-in. twisted steel every 12 in. The working floor of the spillway provides for the thrust at the top.

The Spillway.

The spillway, 42 ft. wide and 5 ft. deep, is in the north tangent. It is fitted with top-hinged, swinging, steel supports or needles, 3.5 ft. from center to center, for supporting ordinary plank flash-boards. It is intended that the ordinary operation of the flash-boards shall be by hand, using hooks on the irons placed for that purpose on the boards. For emergency use means are provided for prying up the needles by using a steel bar kept for that purpose, until the bottom passes the

lower support and allows the needles to swing down stream, thus releasing the boards supported by the needles. In such event the boards released go down stream, and may be lost; but the need for such release is infrequent, and the loss of a few boards of little moment. The spillway apron is from the top of the upper thrust beam to the crest of the spillway; it is arranged to throw the water well away from the dam, where it finds its way to the creek channel without further provision for directing it.

Contraction Joints.

There are only two contraction joints, and they are placed where the arch abuts the tangents. The north joint begins at Elevation 60 and the other at Elevation 80. One side of the joints was built in advance of the other, and a coating of hot, DX-grade, California paving asphalt was applied to the surface before the remaining concrete was placed. Across the joint, and 2 ft. back from the up-stream side, a 1½-in. pipe was placed, one half in each side; when these pipes were removed, a 2-in. hole was left, and this was run full of the hot asphalt, as additional security against leakage. The joints, being on true radial lines, had no dowels or reinforcing steel extending across; but heavy offsets were made in the concrete.

Steel Reinforcement.

No reinforcement was used until Elevation 50 was reached; from that point to the top, 1-in. square twisted steel was placed in 2-ft. squares and 1 ft. back into the concrete on both sides of the arch. The gravity section tangent has no reinforcement, but the deck type of tangent has a reinforcement of ¾ and ½-in. square twisted steel rods. It was decided to use the steel in the manner described as a compromise of apparent demands of the elements involved—the horizontal steel to stiffen the thinner parts of the arch, the vertical to distribute the ice pressures, and all to prevent cracks. It certainly prevented cracks, but more steel may have been used than was strictly necessary. The heavy reinforcement may be warranted in the interests of safety, especially considering ice thrusts, for ice of great thickness forms here.

The gate-house, parapet wall, and gate-tower had a reinforcement of ¾ and ½-in. square twisted steel in all places where its need was evident. The item of structural steel is covered by railings, trash-rack, gate-house doors and shutters, and the spillway fittings. About 90½ tons

of reinforcing steel were used. The greater part of this was in the arch, but a very considerable quantity was used in dowel pins, braces to the gate-tower crossing the surrounding space, as well as in the tower proper and about the gate-house, spillway, and thrust beams; no accurate segregation was made, as all was paid for at one price per pound, regardless of kind or place of use.

The Outlet System.

The outlet system comprises an intake tunnel, a discharge tunnel, a vertical gate-tower in a shaft and carrying three balanced gates, set at the bottom of the tower and at the one-third and two-thirds points of the height, a sump or water cushion at the bottom of the gate-tower, and a hand-operated device in the gate-house for opening and closing the gates.

The concrete tower carrying the gates has an inside diameter of 6 ft.; the walls are 30 in. thick, and the outside diameter is 11 ft. This gate-tower is set in a shaft, 15 ft. in diameter, blasted out of solid rock up to about Elevation 70 and thence to the top forming a part of the north tangent. The annular space about the tower is always full of water, supplied through the intake tunnel; and, on opening a gate, discharge occurs into the 6-ft. opening in the tower, from which it drops to the sump and is discharged thence to the stream through the outlet tunnel. Leading from the reservoir to the annular space in the shaft about the gate-tower is the intake tunnel, 60 ft. long, with a cross-sectional area of 33.8 sq. ft., and with its bottom at the level of the bottom of the lower gate, at Elevation — 5, or 145 ft. below the top of the dam.

The outlet tunnel is also about 60 ft. long, and has a cross-sectional area of 50.2 sq. ft. It is set at a lower elevation than the inlet, and is arranged for a water cushion in the central shaft and a water seal for preventing a draft of air through the gate-tower, thus precluding the formation of ice. This is a matter of importance in this cold place. As it is necessary to draw all water through the old outlet system when the reservoir surface is below Elevation 100, the tunnels were designed to carry only the capacity of the old outlet. It would have been better, perhaps, to have made them larger, in order to avoid excessive velocities with the larger flows possible when the water is higher than the old dam.

The Trash-Rack.

The old outlet had been provided with a light steel trash-rack, and, as it had given no trouble during 18 years of use, a similar rack of ½ by 5-in. steel bars, 5 in. from center to center, was placed at the new outlet. The rack rests on four pieces of 90-lb. rails, spanning the shorter way. When the water was drawn off, in the fall of 1917, it was found that trash which had gathered on the rack had reduced the flow of water until the resulting pressure had bent the steel rail supports and bent and twisted the rack bars. It is fortunate that the rack was not stronger; had it been equal to holding the pressure, a very embarrassing situation would have resulted. No indication of the condition was visible, and it was not suspected until the water was drawn off.

The bent and twisted rack was entirely removed, and the channel between the old and new outlets, about 5 by 5 ft., with an open top, was covered with a grill of pine poles having a minimum diameter of 9 in. These poles have an average length of 16 ft., and span the channel in an inclined position, extending from the outer side of the channel to the rock wall of the cliff on the other side, with clear spaces of 6 in. between the poles. The distance covered is 70 ft. The poles are fastened in place by setting 1-in. steel pins in the rock and using ties of No. 9 galvanized wire. This arrangement has not yet been tested, but promises good results.

The Cylindrical Balanced Gates.

Each gate works in a cast-iron ring or cylinder set in the concrete walls of the gate-tower. Each cylinder has six 2 by 2-ft. openings in its perimeter, and these are symmetrically spaced. Freely movable vertically inside of the stationary rings are the gates proper, which are cast-iron cylinders with no openings. When the gates are fully down, the openings in the outer cylinders are closed. At the tops and bottoms of the cylinders are fitted heavy rings of naval bronze; when the inclined faces of the bronze come in contact, a water-tight joint is formed.

This arrangement insures a perfect balance of water pressures. Use has demonstrated that no more force is required to operate these gates under pressure from full heads of water than when there is no pressure. Hand-wheels are all that are needed for operation; the arrangement

provided for the purpose works very easily, and with such smoothness and speed as to call for nothing better; power operation would be of no advantage.

There are two stems, of $3\frac{3}{16}$-in., cold-rolled steel shafting, rigidly attached to opposite sides of each gate, extending up to the operating gears and below each gate, to form guides to steady them and assist in keeping them in position. The stems of the lower gates pass through holes in the castings of the upper gates, and all are provided with bronze-lined guides every 12.5 ft. in height. The top guides have feather keys, in order to prevent turning, and the bronze linings have a clearance of $\frac{1}{4}$ in. to allow for incrustations. The upper gates, when opened, discharge through the lower gates, and the small projections of stems and guides do not interfere with the discharge.

The tops of the stems are threaded with single square threads, three to the inch, working in heavy bronze nuts with thrust ball-bearings above and below the nuts. The hoists are arranged to operate the two stems of each gate at the same time by using one hand-wheel, having a gearing of cast iron with machine-cut teeth. The stands carrying the gearing are set on a heavy cast-iron ring with brackets, in such a manner as to leave a large opening at the top of the shaft for supplying air to overcome the strong suction caused by the discharging water. The need of this is shown by the fact that, when the gates are discharging, it is very difficult to open the steel door to the gate-house against the air pressure, notwithstanding the generous supply of air through the top ventilator on the gate-house provided for that purpose.

The wisdom of making the stems much heavier than called for by their computed tensile strength is shown by the accidental lodging of a 5-ft. length of 6 by 8-in. timber in the lower gate in some unaccountable manner. An attempt to close the gate showed that something was wrong, for before one man had nearly exerted his full strength on the hand-wheel, the heavy cast-iron top ring was started from its anchorage. When the reservoir was emptied, it was found that the timber was cut at least half way through. Lighter stems could not have withstood such abuse without being damaged.

The Concrete.

The Red Devil brand of cement, manufactured at Devils Slide, Utah, was used throughout. The cement passed the tests satisfactorily,

and it was unnecessary to reject any. A complete apparatus for testing cement and concrete materials was provided at the work, one man being constantly employed on tests.

The sand available had a very forbidding appearance, for it had a large content of fine silt and clay, and, when made into a cement mortar, presented a "muddy" consistency, but tests showed a fair strength and a good degree of water-tightness. Crushed rock was used for the coarse aggregate.

All the tests for strength were made by breaking mortar briquettes in a tensile testing machine. It is fully realized that such tests are properly only tests for cement combined with sand as mortar, and not true tests of concrete made with such mortar and under compression. The true test for concrete should be made in a compression machine of sufficient capacity to crush 8 or 10-in. cubes or cylinders made of the concrete used on the work, including the coarser aggregate. It is probable that the cost, large size, and weight of such compression machines is a bar to general use, as was the case in this instance.

Tests of mortar composed of the cement and sand showed a satisfactory increase in strength with age, some breaks in specimens of 1 cement to 3 sand running as high as 500 or 600 lb. per sq. in. at the age of 3 months.

Briquettes were made from the mortar from the mixer nearly every day concrete was placed. No breaks could be made at 2 days. At 7 days the tensile strength showed an average of about 100 lb.; at 28 days it was always more than double the strength at 7 days; and at 18 months the minimum was 310 lb. and the maximum 645 lb., with the average running about 500 lb. Breaks were made frequently between the 28-day and 18-month periods, and in no case was there a failure to show an increase of strength with time.

Notwithstanding the bad appearance of the sand, containing as it did much earth, clay, and silt, the outcome is very satisfactory, although more cement was used than would have been the case had clean sand been available. It is now known, however, that this concrete is more water-tight than if made with all screenings. All the concrete was mixed with more water than desired, in order to help in placing it in the forms and avoid the formation of rock pockets without mortar. It is well known that with fresh concrete, made with clean sand, the cement will be washed away by the least contact with water. Some concrete

in the foundation was placed in water without harm, or any loss of cement, and several times, when the pumps stopped, the surface of fresh concrete was flooded without bad effects, which would not have been the case with concrete made with clean sand.

The proportions of the concrete used in the body of the dam were, as nearly as possible: 1 part cement; 3 parts sand, with some screenings through a ¾-in. screen; and 5 parts broken rock, 3-in. maximum size.

In the body of the dam 4.75 sacks of cement per cu. yd. of concrete were used, and for about 800 cu. yd. about the gate-tower, for tunnel lining, and in the gate-house, the quantity was 6.25 sacks per cu. yd. It was planned to use plum rock in the concrete of the dam body, but cold weather prevented, as it was too difficult to remove the snow, ice, and dirt from the rock.

Concrete in Cold Weather.

Most of the sand was hauled early, and was in a large pile on the side-hill above the bins; and becoming wet from the fall storms, froze to a depth of 2 or 3 ft. The broken rock was coated with frozen earth, snow, and ice. Notwithstanding the fact that the bins were roofed over, the materials often froze together. Nothing was done to overcome these conditions except to mix the concrete with hot water. The concrete as it came from the mixer was just above the freezing point, and, to maintain it at this temperature, it was necessary to keep the water hot and throw out the larger, solidly frozen lumps.

Experience soon showed that the rise of temperature due to chemical changes in setting prevented damage from frost when the concrete in the forms was covered at night. Canvas was spread over the forms, steam jets prevented surface freezing, and the temperature of the mass below the surface soon increased sufficiently to remove any frost occurring there, if not too great in quantity. The steam caused heavy deposits of frozen moisture on the forms; when this melted it caused a very sloppy condition, and so the steam jets were abandoned and salamanders burning coke were substituted, with an improvement of conditions. When concrete was placed on colder days the surface of the fresh concrete often immediately froze over to the depth of an inch or two. It was found that placing fresh concrete thickly over such a surface, quickly thawed it out without harm; but when the freezing was too severe, the frozen part was picked, broken up, and thrown out. Steam

jets were used freely to thaw out and remove the ice from the forms, concrete surfaces, and rock walls, immediately before placing concrete against them.

The removal of the 1½-in. pipes in the contraction joints afforded a very favorable means of testing the rise in temperature in the concrete when setting. Tests of temperature by lowering a thermometer into the holes showed in every case a considerable rise, a typical test showing a temperature of 70° Fahr. at a depth of 15 ft. when the air was at 14° Fahr., a difference of 56 degrees.

The Forms.

The use of forms began at Elevation — 10. Up to that point the excavation was filled to the sheeting. The forms were built in sections 10 ft. high. At the top and bottom of each form 2 by 10-in. plates were placed, and vertical pieces of the same dimensions were set between as studs, 2 ft. from center to center, with 1 by 6-in. sheeting on the studs. At the jointing of the sections horizontal 2 by 6-in pieces were spiked to each stud, projecting 4 ft., with a 1 by 6-in. brace from below. These brackets formed a place for a working scaffold, and braces upward from the end helped to place the next section of forms.

When a form was filled to the top with concrete, and before it had set, 1-in. steel pins, 4 ft. long, with an eye at the top, were driven into the concrete, about 6 ft. in from the forms. Ties of 4-ply, No. 9 wire, were strung through the eyes in the pins and fastened to each stud at their one-third points of height, thus being inclined sharply upward. The wire ties were then twisted to tightness, and served to hold the forms true against the pressure of about 2 ft. of freshly deposited concrete; the concrete was accordingly placed in layers of about that thickness, moving back and forth as necessary to avoid excessive pressure and the resulting bulging of forms. No wires were allowed to reach from side to side of the dam. Where the thickness of the dam was greatest, two rows of anchor-pins were used, and only one row when the distance between the forms became less. Near the top, in the narrower space, the use of two rows was resumed, with the stay-wires crossing in order to keep proper distance from the forms; at the very thinnest part the wires were attached to the reinforcement. The forms about the gate-tower, spillway, and gate-house presented no special features, being of the usual 2 by 6-in. studs, 1-in. sheeting, and wire ties. Figs. 4, 5, and 6 show the formwork and the complete dam.

The Plant.

The plant presented no unusual features, for it consisted only of ordinary steam-driven machinery, and was all adapted to use on this work from such as the contractors had left on hand from previous jobs. The excavation was dewatered by three 8-in., belt-driven, centrifugal pumps. Rock drilling was done by machine drills driven by compressed air. Compressed air was also used to drive some of the hoisting engines for the derricks. Rock crushing was done by medium-sized jaw crushers, and all materials were handled by gravity. Concrete was mixed in ¾-yd., Smith mixers, and conveyed by metal-lined chutes to steel mining cars running on a light track on top of the forms.

Cost of the Work.

Table 1 is a detailed statement of the cost of the work, with quantities and unit prices.

TABLE 1.—Cost of the Work.

Tunnel and Shaft Excavations:					
Neat section	860.4 cu. yd.	@	$5.40	$4 646.16	
Overbreak	123.1 cu. yd.	@	2.16	265.90	$4 912.06
Foundation Excavation, above Elevation —35:					
Neat section	1 623.9 cu. yd.	@	$2.50	$4 059.75	
Overbreak	825.8 cu. yd.	@	1.00	825.80	4 885.55
Foundation Excavation, below Elevation —35:					
Neat section	547.7 cu. yd.	@	$5.00	$2 738.50	
Overbreak	53.6 cu. yd.	@	2.00	107.20	2 845.70
Hauling Cement: 19 170 bbl. @ 87½ cents					16 773.75
Reinforcing Steel: 181 200 lb. @ 3½ cents					6 342.00
Concrete: 15 888.38 cu. yd. @ $5.25, including forms					83 414.00
Cement: Furnished by the owners					35 742.24
Concrete Lining: tunnels and gate-shaft, 590 sq. yd. @ $1.45					885.50
Balanced Cylinder Gates					6 250.00
Sundry on Contract: Force account				$8 713.70	
Lumber left in excavation				450.00	
Extra formwork				500.00	
Structural steel				938.98	10 602.68
Inspectors on Concrete					778.15
Lands Purchased for Reservoir					3 423.80
New Road Around Reservoir					5 278.60
Total					$182 134.03
Engineering, 6.15%					11 217.24
Total Cost					$193 351.27

The cost per acre-foot was $6.90. The cost of the concrete was $6.37 per cu. yd. The engineering cost covers all preliminary work from the beginning.

Conclusion.

In the season of 1916 the water in the reservoir was raised only to the 100-ft. level, for the concrete work was too new to be put under full pressure. In 1917 the dam was full to the top, and a heavy flow wasted over the spillway. It is estimated that the water-shed furnished some 60 000 acre-ft. in that season. During the season of 1918 the entire yield of the water-shed only filled the reservoir to the 120-ft. contour. The dam has thus been fully tested. The gates have passed at times as much as 600 sec.-ft. without shock or jar. In the fall of 1917 the reservoir was completely emptied and the structure carefully inspected. Not a single crack or defect was visible; no sign of weakness, incipient disintegration, or scaling of concrete could be found. The sump was baled out, and it was found that the water in heavy flows falling from a height had not injured the concrete or rock in the slightest degree, the only thing needing correction was the trash-rack, as already mentioned. When there is no water back of the dam, the contraction joints open about $\frac{3}{8}$ in., but, as the water rises, the joints gradually close tight.

Although resting on good, solid, water-tight rock, and joining it on the sides, there were several bedding places and cracks that threatened leaks around the dam. It was not attempted to stop these, because small leaks could do but little damage, beyond loss of water, and it was decided to try them out. As the reservoir was filled, and when the water was about 70 ft. in depth, two leaks appeared on the walls of the canyon, on the south side and about 75 and 125 ft., respectively, down stream from the dam. The combined flow of the two leaks is estimated at 2 sec-ft.; it is impractical to measure them. When the dam was first put under water pressure there was a heavy seepage or percolation through the concrete, heaviest at the horizontal joinings between concrete forms, but all rapidly reducing in quantity until the percolations were so small that they only showed when in the shade; when the sun shone on the surface it became dry. There was not one leak through the dam or its joining with the rock, nothing more than the percolations mentioned.

The seepage brought to the surface salts from the cement, and they cause a streaked efflorescence on the back of the dam; this is very plainly in evidence, and presents a false appearance of leaks that is very misleading, especially in a picture. That there are no leaks is shown by

the fact that when the gates were first closed, and until the appearance of the two small leaks mentioned, the flow of the creek was reduced so much that the Fish and Game Commissioner demanded that more water be admitted in order to keep the fish from being destroyed. Accordingly, a gate was opened a little.

When the dam was built it was necessary to leave a hole, 2 ft. square, through it at the lower gate level. This was stopped temporarily by a timber bulkhead. It is planned to place a 14-in. pipe in this opening, and, at the down-stream end, a heavy valve. The latter will be covered with a concrete house to guard against frost and meddlers.

As it is important to know the exact depth of water back of the dam, and its rate of rising or falling, a special device for this purpose has been designed. A heavy copper float, guided by two copper wires set vertically in the annular space about the gate-shaft, is suspended by a plated steel tape; the latter is wound on a 28-in. drum geared down by two reductions to the point where 50 ft. of movement of the tape will cause a movement of 1 ft. on the balancing weight. A wooden rule, 1 ft. long, is attached by the side of the tape to read the fractions of feet. It has not yet been tested, but promises to give good indications of small variations in depth, as this information is most important in the operation of the reservoir.

In spite of the unfavorable conditions of weather under which the dam was built, the fine clayey sand used, and the slight appearance of the arch, it may be pronounced a very successful structure. The contractors are entitled to credit for their faithful prosecution of the work under adverse conditions, and for their patience, courage, and fidelity to the interests of good work. The structure was not plastered or patched, but remained just as the forms left it, and with no deviation from true lines; no places show in the least careless or hasty work.

Credit is due to Samuel Fortier, M. Am. Soc. C. E., who, being familiar with the old dam and the conditions of the site, endorsed the building of the new structure. He also gave much valuable advice about its design.

The work was done by the Utah Construction Company, of Ogden, Utah, Mr. A. J. Sartoris, of Oakland, Cal., being directly in charge as Superintendent. Mr. H. F. Irwin was the writer's representative on the job.

DISCUSSION

Mr. Godfrey.

EDWARD GODFREY,* M. AM. SOC. C. E. (by letter).—Mr. Parker has shown wisdom in selecting a low unit stress for the concrete of this arch dam. Reduced to square inches, this unit stress is 174 lb. It is true that there are venturesome souls who would use concrete stresses as high as 850 lb. per sq. in., as Mr. Parker states, and these men call themselves engineers because they spend one dollar where others would "squander" several.

From the achievements of structural steel designers, in which factors of safety are sometimes about two or less (the elastic limit being considered the point of ultimate usefulness), an argument might be constructed for higher units in concrete, which would look plausible enough on its face. Steel and concrete, however, are quite different in their behavior.

If a dam begins to show signs of weakness, it does not help matters to post notices to reduce the loads, as in the case of failing or inadequate buildings. There are many buildings and other structures which never receive the loads they are supposed to carry. Some of them would collapse if they did.

There are many arguments for conservatism in the selection of unit stresses in the design of a dam, chief of which, of course, is the dire consequence of its failure. Next comes the argument as to the certainty of the realization of the load (already hinted at). Other reasons for low unit stresses will be mentioned later.

Unit stresses in dams received little notice in the days when gravity dams were built almost exclusively. Much was written some years ago concerning shear in a gravity section, but this was in the days before under-pressure began to be recognized as a factor to be considered in the stability of dams and a cause of most failures. If a gravity section is properly designed for under-pressure, in construction joints and beneath the dam, vertical shear in wide-spreading toes need give no concern, for those toes will have no existence.

When hollow dams and multiple- or single-arch dams began to be built, more care was necessary in the matter of unit stresses. Even then, and before and since that time, the one great essential in design was often neglected, namely, the applied loads. It would seem to be a simple matter to know and provide for the pressure of water, for that pressure is so sure, and obeys laws that are quite well known. In spite of this, there is not a book in the English language (excepting very recent ones) that even mentions the great force of water in horizontal joints and at the base of a dam. Consequently, an engineer is at a disadvantage in designing a dam, especially when he sees elaborate calculations to find the true theoretic cross-section, that

* Pittsburgh, Pa.

Mr. Godfrey.

ignore entirely forces of tremendous moment which render these calculations utterly void. Mr. Parker's paper does not state that he considered under-pressure. It is true that this does not affect the stability of an arch dam so vitally as it does that of a gravity dam or a hollow dam; but, if the section of an arch dam should be so light that its weight would approach that of a prism of water conceived to be constructed on its base, a danger point is reached where the dam is likely to be raised from its base and thus allow water to work beneath it, a wash-out resulting. If the dam had other than a good solid end abutment, settlement at the arch ends might aid to raise the base at the crown of the arch ring. This is one of the reasons for using low units in the arch ring. The low unit will mean greater thickness of the latter and greater weight and stability for the dam.

Consideration of under-pressure, also, ought to lead to a design in which the batter is on the up-stream face, for such a batter adds to the pressure on the foundation by the amount of the weight of the water lying vertically over the battered face. Furthermore, a batter on the up-stream face tends to throw the end thrust of the arch downward, instead of in a horizontal direction, thus adding to the stability of the arch. Mr. Parker has made the greater part of the batter on the down-stream face. In the tangent portion the batter should be made on both faces, in order to obtain the spreading effect at the abutments, but, the writer is of the opinion that the stability would be greater if all the batter were made on the up-stream face in the arch portion.

Another reason for reducing the unit stress of an arch of this length is expressed by the term "column action". The arch resembles a column of very considerable unsupported length, just as a hollow tube under external pressure resembles such a column. A tube under external pressure acts about as a column of a length (hinged-ended) equal to half the circumference. Therefore, the ring of an arch dam should be treated as a column, and its length is equal to that of the arch from abutment to abutment. Of course, support is offered by the base of the dam. This is similar to the support afforded to a wide flange of a girder by the stiffness at the root of the flange. The arch dam is not, as some have claimed, equivalent to a short column.

Just what reduction should be made in unit stresses for wide, thin flanges is not very well understood or codified by structural engineers. A rule used in the case of girder flanges is to limit the thickness to one-twelfth of the width of the outstanding leg. Girder flanges are generally otherwise stiffened at intervals, and their maximum stress occurs only throughout a small portion of their length. The dam should be designed on a much safer basis than this, because, first, concrete has not the toughness of steel; second, the full stress exists from end to end of the arch; third, mere support on the earth is not

Mr. Godfrey.

equivalent to the strength at the root of a girder flange angle; and fourth, there are no braces at intervals in the arch dam. Mr. Parker's dam has a ratio of height to base thickness of six or seven, due to his commendable selection of a low unit stress. If he had elected to adopt the high unit stresses favored by some designers, the writer is of the opinion that the result would have been hazardous.

Another reason for low unit stresses is the uncertainty regarding the distribution of the stress throughout the section. Shrinkage of the concrete, expansion due to moisture, or changes due to varying temperature, are sure to result in unequal distribution of compressive stress on the section of the dam. The great length of the dam would make these variations of greater magnitude in this than in a smaller structure.

Hollow dams have proved most forcibly, by four notable failures, that the type having a bottom slab resting on the soil is an error. Three of these dams failed in winter, when, presumably, the weep-holes were frozen up; in the other case the weep-holes had been plugged up in order to save water. Upward pressure caused the failure of these hollow dams. It does not act to overturn them, but merely lifts them from the soil and thus permits the passage of water beneath the dam, which washes away the foundation, and failure results. Part of Mr. Parker's dam is hollow, but, fortunately, there is no bottom slab joining with the inclined slab, and the solid portion has considerable weight. It is probable that the rock formation is such as to preclude the possibility of water pressure under the solid portion being communicated across the gap between the inclined slab and the solid bottom part of the dam.

If this separation of the inclined slab and the solid bottom is intentional and general (and not merely accidental in the section, Fig. 3), it is fortunate, as it differentiates this dam from the hollow type which has furnished the four failures referred to.*

There is also considerable mass in the hollow portion of Mr. Parker's dam, and that helps to hold it down against upward pressure. Mr. Parker has used dowels to anchor the concrete to the masonry. Such dowels might help, but the writer would not be inclined to place much confidence in them, either for this purpose or for preventing the slipping of the arch abutments, where the line of thrust makes a rather sharp angle with the rock face. For the latter he would prefer to blast out the rock face in steps, the several steps being nearly normal to the line of thrust, or holes might be blasted for keys in order to prevent slipping. If he were building on a sloping rock, he would not wish to trust to dowels to prevent the structure from slipping down the slope, but would cut steps in the rock.

* Pittsfield Dam, *Engineering News*, April 1st, 1909; Dansville Dam, *Engineering Record*, January 1st, 1910; Stony River Dam, *Engineering News*, January 22d, 1914; and Plattsburg Dam, *Engineering News*, June 8th, 1916.

Mr. Godfrey. In the north tangent the thrust is carried by rectangular columns or shafts between the piers. These members are reinforced with steel rods. The compression on these members is about twice as great as that on the arch ring. Twisted steel rods, 1 in. square, are placed longitudinally in these members, for the purpose of taking compression, and these rods are surrounded by what Mr. Parker calls hoops. It is unfortunate that the term "hoop" should be applied to a piece of steel bent in a rectangular shape. It is more unfortunate that it should be imagined that such pieces of steel can act in a manner similar to hoops in a hooped column. A mere term can be used in such a way as to create a false sense of security (witness the term "column" applied to two little channels tied together with small battens at intervals). A hooped column is a properly reinforced concrete member in compression, but, a member with rods disposed in a rectangle with square ties at intervals of about 12 in. is not a hooped column, and is not properly reinforced. The rectangular tie can only act to hold the four corner rods against lateral displacement, and the intervals between such ties should be closer than 12 in. in a properly hooped column.

Again, twisted rods are not of the proper shape for compression members; they should be as straight as possible.

Of course, the unit stress in these columns is not great, but, in the writer's judgment, it would be better to make the section of these members as large as that of the arch, and to use steel merely to tie the concrete together, and not to take compression.

The rodded column is the most discredited piece of construction that can be named. In almost all of more than a score of bad reinforced concrete wrecks rodded columns have proved their unfitness. Many large and chunky columns, carrying trifling loads, have broken into pieces, instead of standing and sustaining their share of the load.

Mr. Fortier. SAMUEL FORTIER,* M. AM. SOC. C. E. (by letter).—As the author has stated, the East Canyon Creek Dam forms part of a co-operative irrigation enterprise known as the Davis and Weber Counties Canal Company, which is owned and controlled by a community of farmers occupying the "Sand Ridge" immediately south of Ogden, Utah. For the past twenty-eight years, the writer has acted first as consulting engineer and, later, as adviser of this Company. The knowledge thus gained of the efforts made by its stockholders during the past quarter of a century to store water for irrigation purposes, is his only excuse for presenting in brief form a few ideas on two phases of this subject, *viz.:*

1.—The advisability—when financial and other conditions warrant —of designing and building dams to impound water for irrigation purposes in progressive stages.

* Berkeley, Cal.

2.—The advantages—where physical conditions permit—of building abutments of gravity section on each side of a canyon at the dam site, and confining the arch to the central portion of the structure. Mr. Fortier.

The first of these phases can best be considered in relation to the enterprise under discussion. In August, 1894, the writer made an examination of the dam site described by the author, and recommended that the company purchase the site and proceed to utilize it to the extent of the funds available and the credit then obtainable on the part of the company; and this was done. As rock was abundant and easily obtained, the writer recommended a loose rock dam having a steel core protected by asphalt concrete. The site selected by the writer lay well within the canyon, but, in excavating for a foundation, the officers of the company shifted the site near the upper entrance to the canyon, with a view to lessening the cost of building the foundation. Most of the troubles which subsequently affected this structure were directly traceable to this change of location. The original dam had an effective height of 58 ft. and formed a reservoir with a capacity of 3 850 acre-ft.

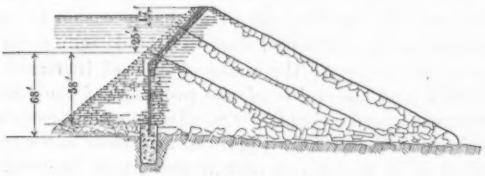

FIG. 7.

The topography of the site selected was well adapted to this comparatively low dam, but it was unsuited to the additions to the structure afterward imposed on the original. In 1900, the capacity of the reservoir was increased to 9 000 acre-ft. by raising the dam 25 ft. This increase could not be made by extending the steel core in a vertical direction, for the reason that the upper portion of the steel core as well as the upper portion of the rock-filling would have lain outside the canyon. (See Fig. 1.) Accordingly, the steel plates forming the core were inclined down stream at an angle of 45 degrees. Two years later, when the capacity of the reservoir was increased to 14 000 acre-ft. and the effective height of the dam to 100 ft., there seemed to be no other course than to place all the additional rock material on the down stream, as was done before, and continue the extension of the core-wall at the same inclination to the vertical. A cross-section of the original dam and the two additions is shown on Fig. 7.

In calling attention to the weakest feature of the old structure, it is only fair to add a word bearing on the success of the enterprise as a

Mr. Fortier.

whole. Before stored water from the reservoir was available, the farmers under the system were not in a prosperous condition. Being one of the late appropriators on the stream, the company was entitled to a portion of the annual flow of Weber River only when there was a surplus. Usually about July 1st of each year, when the discharge of the river was needed by prior appropriators, the company was compelled to close its head-gates and to keep them closed throughout the remainder of the crop-growing season. In consequence, only grain and partial crops of fodder could be raised. Neither orchard trees nor late vegetables could be grown with any assurance of success. With so limited and unreliable a water supply, the farmers could not produce the most profitable crops. At that time, the price of improved farming land under the system ranged from $10 to $30 per acre. Water stock of the company having a par value of $50 per share, was not worth more than $10 to $12, and a fair valuation of the property of the company would not have exceeded $250 000.

The use of water stored in the East Canyon Creek Reservoir gradually improved these conditions. As has been stated, the quantity stored was at first relatively small, but, in 1902, it had been increased to nearly 14 000 acre-ft. In 1910, the writer had occasion to examine the affairs of the company and found improved lands selling for $300 and more per acre, the value of the water stock had increased from $12 in 1896 to $175, and the value of the property of the company was conservatively estimated at $1 000 000. During the past eight years, the affairs of this company have improved at a more rapid rate than at any like period of its history, so that at present its financial condition is highly satisfactory.

This much of the history of this enterprise is cited in order to call attention to the feasibility and economic soundness of building dams to store water for irrigation purposes in progressive stages. Considered in the abstract and without reference to local conditions, most engineers would be inclined to condemn such a course as unsafe and unsound, and they might with reason undertake to prove the accuracy of their viewpoint by this same enterprise.

Here is a company that built a dam in 1896 at a cost of more than $50 000, enlarged it in 1900 at a cost of $35 000, enlarged it a second time in 1902 at a further cost of about $25 000, and, in 1915 and 1916, built a new structure from the foundation up at a cost of $193 000, thereby abandoning the greater part of the old structure. Thus, in a period of 20 years, $303 000, exclusive of interest charges, had been expended in storing water. At first sight, it would appear that good engineering practice as well as economy would have called for the construction in the first place of a permanent dam of ample capacity at a cost of less than $200 000.

Mr. Fortier.

It is not difficult to show that such a course was impracticable, under conditions then existing, and even if it could have been done, of doubtful economy. The financial condition of the company in 1896 precluded the possibility of raising anything like $200 000 to store water. It was difficult to bond the property to raise $50 000 in order to provide funds to build the original dam. The interest on these bonds was 7½% per annum. Accordingly, the company would have been obliged to abandon the idea of storing water. Some other organization in all probability would have secured the valuable site on East Canyon Creek, and, to-day, the financial status of the Davis and Weber Counties Canal Company might have been in no better shape than it was prior to 1896.

For the sake of argument, let it be assumed that the stockholders of the company were in a position in 1896 to bond their property to construct a dam capable of impounding 28 000 acre-ft. In the light of subsequent developments, would this course have proved economically sound? The writer does not think so. With the possible exception of the period from 1896 to 1900, inclusive, the water users of the enterprise had sufficient water to meet their requirements and to provide for normal expansion. Unless the surplus could have been sold to other parties, the greater part of the 28 000 acre-ft. stored could not have been utilized. Furthermore, to base an estimate on what actually occurred, it is doubtful if much more than one-half of the storage of the large reservoir would have been utilized for the first 20 years after completion. In the meantime, the unused portion of the stored water would deposit its quota of silt within the reservoir and lessen to that extent its holding capacity.

Furthermore, during this 20-year period, the interest on the cost of a dam capable of impounding 28 000 acre-ft. in excess of the interest on the expenditures actually made in storing water in progressive stages, would have amounted to a large sum. The following figures may convey some idea of this extra interest charge on the basis of 7½%, compounded annually:

Interest on	$193 000	for	20	years.....		$626 900
Interest on	50 000	"	"	"	$162 410	
Interest on	35 000	"	16	"	76 335	
Interest on	25 000	"	14	"	43 815	282 560
	Balance					$344 340

This accounting of the two methods of building dams for the storage of water shows a balance of $344 340 in favor of the plan actually followed. Even when the rate of interest is reduced to 6% per annum,

Mr. Fortier.

which corresponds more nearly to current rates for such undertakings, the balance in favor of the same plan would still be $230 170.

In order to be understood, it should be stated that the building of dams in separate stages or additions, as herein advocated, might not be economically sound if all the water stored by such structures could be utilized soon after completion. Such a course applies in particular to water stored for irrigation purposes, for the reason that long periods of time usually elapse before even one-half the volume of water stored is utilized. The profile, Fig. 8, based on the returns of the 13th Census, shows the average rate of settlement of irrigation enterprises in the United States.* The profile is based on data secured from 522 enterprises, each containing 5 000 or more irrigable acres. Generally

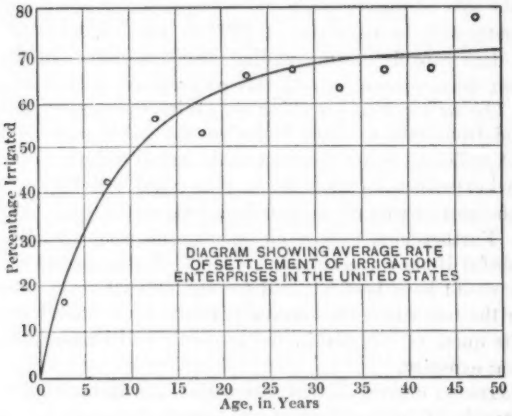

FIG. 8.

speaking, the larger the project, the slower the rate of settlement. Experience has shown that in projects containing 25 000 or more acres, a period of 20 years elapses on an average before 50% of the lands are settled.

In reference to the second phase, in which it is proposed to use a combination of two types of dams, the writer believes such a plan not only feasible but desirable where conditions are suitable.

The nearest approach to this combination type of concrete dam, in so far as the writer is aware, was first made use of by H. Hawgood, M. Am. Soc. C. E., in the design and construction of the Huacal Dam at Nacozari, Sonora, Mexico.† To quote Mr. Hawgood:

* "Irrigation in the United States," by R. P. Teele, D. Appleton Company, New York.

† *Transactions*, Am. Soc. C. E., Vol. LXXVIII, p. 564.

"The dam is not of the arch form for its entire length. For 42 ft. at its southeasterly end it is of gravity section, and in direction tangential to the curve." Mr. Fortier.

He also gives the reason for building a small portion of this structure in this manner, by stating:

"The continuance of the dam on a curve throughout its entire length would have brought the direction of its easterly end too closely parallel to the axis of the canyon to have been economical or safe."

When the writer was consulted in reference to the design of the East Canyon Creek Dam, he did not know that abutments of gravity sections had ever been used in connection with single arch dams. When the plan was proposed by Mr. Parker, the writer gave his approval and urged that both abutments be of this type, but owing to the formation of the rock at the north end, a hollow-deck section was substituted.

As a result of his observations of the behavior of the East Canyon Creek Dam during the past three years of operation, and his knowledge of dam sites throughout the West, the writer is of the opinion that a new type of combination dam might be developed, in which the abutments of the gravity sections at each end might well be enlarged in the case of spans longer than those of the Huacal Dam or the East Canyon Creek Dam.

A typical cross-section of a canyon at a dam site throughout the mountainous portion of the Far West, based on the observation of the writer, is shown in Fig. 9. It will be noted that the lower portion extending from bed-rock to nearly one-half the total height, is relatively narrow, with nearly vertical sides, and is filled more or less with sand, gravel, and boulders. From this point the sides slope in the form of the letter V as far as the sides of the canyon rise. Every engineer who has tried to design an arch dam that will fit into these conditions and be adapted equally as well to the narrow lower portion as to the flaring upper portion, has encountered difficulties. Maintaining a constant angle by varying the radii of the arch is only a partial solution, for, as the author has pointed out, cases are rare where it is possible to maintain a constant angle between the limiting radii.

The writer invites the attention of hydraulic engineers to the combination arch and gravity section type as one method of designing concrete dams to conform to cross-sections of sites such as are usually found in deep, rocky canyons. Referring to Fig. 9, the triangular portions, *ABE* and *CDF*, are to be designed as gravity sections, whereas the central portion is to constitute a single arch of substantially equal radii throughout its upper portion, if not throughout its entire height.

Some of the advantages possessed by the type of dam herein proposed are based on the following facts:

1. The central portion of gravity dams, comprising from one-quarter to one-third the total span, is by far the costliest to

Mr. Fortier.

build, owing to the height and width of base, which require a relatively large quantity of material.

2. By introducing an arch instead of a gravity section in the costliest portion of the dam, the compressive strength of the concrete rather than its weight is utilized, thus increasing the strength of the structure and lessening its cost.

Beside the saving in cost, this combination type of dam possesses, it is believed, other advantages, of which the expansion and contraction joint is one. It is now quite generally conceded that concrete requires such joints, and concrete dams are no exception to this rule. In the type under consideration, more than ordinary facilities are afforded to make ample provision for both expansion and contraction where the two types come together. Where the arch span is of small or medium

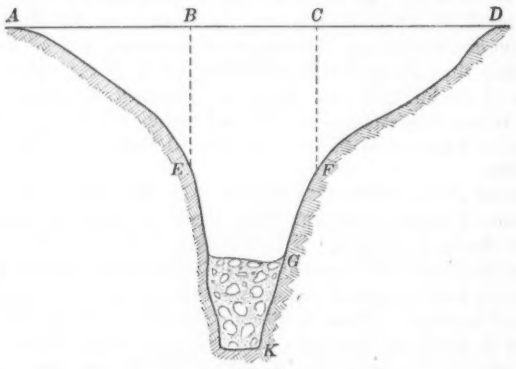

FIG. 9.

length, a joint at each end together with the usual steel reinforcing and the deflection of the arch under pressure should be ample to prevent cracks as well as harmful strains. The experience gained in observing such joints in the East Canyon Creek Dam leads to the conclusion that they are much more effective than those commonly used in all-gravity dams.

Another advantage of this type is its adaptability to the plan of building dams for irrigation purposes in two or more stages, as advocated previously in this discussion. Referring again to Fig. 9, it is readily seen that the foundation and that part of the superstructure up to the height, *F*, might well constitute the first stage. Subsequently, one of the abutments, in whole or in part, followed in time by the other, might be built. Lastly, the construction of the central arch would complete the undertaking.

Mr. Fortier.

In conclusion, the writer would call attention to the popularity of arched dams in recent years, notwithstanding the fact that relatively few dam sites are adapted to this type. In the foregoing, he has attempted to outline how dam sites in canyons which have not been properly formed by Nature for such purposes, can be built up in such a way as to afford ideal sites for single arch dams.

Mr. Wiley.

A. J. WILEY,* M. AM. SOC. C. E. (by letter).—The writer is particularly interested in this complete and satisfactory description of a simple arch dam of unusually great height, because of his experience with a dam of this type where the element of safety was not so important.

The Crowley Creek Dam is in Malheur County, Oregon, on a small stream, in a locality remote from settlement, where the only loss from failure would be that resulting to the owners who were willing to take any reasonable risk, in order to reduce the cost of the structure. The site was in a narrow canyon where an arch dam of short radius could be used. The foundations and abutments were of lava rock, and the only feasible location for the spillway was over the top of the dam. The design prepared by the writer was for a concrete arch dam, 60 ft. high above the stream bed, with a radius of 70 ft. The thickness on top and for 30 ft. below was 3 ft. At the base, 60 ft. below the crest, the thickness was 5.2 ft.

The Malheur Land and Livestock Company, for which the designs were prepared, had the dam staked out by an engineer, and employed a local contractor with some experience in concrete work to superintend the work, using the writer's plans and specifications, but without any further engineering aid. The work was carried to a height of 55 ft. above the stream bed in October, November, and December, 1907, and left at this height for a number of years.

The concrete was composed of Portland cement, sand, and gravel of a poorly graded lava character obtained from the creek bed, and the sand was rather fine and very dirty. About the only thing that could be said in favor of either sand or gravel was that they were the best that were available. Cement was used in the proportions of 1 bbl. to 1 yd. of concrete, and enough sand was used with the gravel to make a workable mix. Inspection after completion of the dam shows that little, if any, excavation was made in the rock base for the foundation, and the alignment was so seriously at fault that the radius at the top varied from a minimum of 58 ft. to a maximum of 80 ft.

The length of the dam on top was 170 ft. and, as no contraction joints were provided, a contraction crack opened at the middle point of the dam. This crack was about $\frac{3}{4}$ in. wide at the top of the dam

* Boise, Idaho.

Mr. Wiley. in cool weather, with the reservoir empty, and closed as the reservoir filled. The maximum overflow was about 2 ft. in depth and included large blocks of thick ice.

In September and October, 1915, under the supervision of Mr. A. T. Ingalls, of Boise, Idaho, an additional 15 ft. was placed on top of the dam, giving it a total height of 70 ft. above the stream bed or 10 ft. above that for which it was originally designed. It was intended that the dam should have no reinforcement, but in order to provide to some extent against temperature stresses, the engineer placed a 1-in. square bar at each 3 ft. of the 15-ft. increase in height.

It was found impossible to correct the poor alignment of the original work, so that the top of the completed dam has almost as great a variation in curvature and radius as that work.

Table 2 shows the thickness and the stresses, in tons per square foot, by the formula for thin arches, for various heights of dam for a radius of 70 ft. and for the depth of 2 ft. of overflow to which the dam has been subjected.

TABLE 2.

Depth below crest.	Thickness, in feet.	Stress in Concrete:	
		Tons per square foot.	Pounds per square inch.
0	3.0	1.45	20
10	3.0	8.75	122
20	3.0	16.00	224
30	3.0	23.30	324
40	3.0	30.60	425
50	3.6	31.60	440
60	4.4	30.80	430
70	5.2	30.30	420

The foregoing description is given to illustrate the abuses to which an arch dam sustaining high unit stresses may be subjected without failure.

The writer is also interested in the simple and efficient outlet works used at the East Canyon Creek Dam. This type of tower outlet controlled by three sets of cylindrical balanced valves, as described by the author, was, the writer believes, first used on the Oakley Dam, of the Twin Falls Oakley Land and Water Company, near Oakley, Idaho, and was designed by the writer in co-operation with J. L. Savage, M. Am. Soc. C. E. These outlet works were fully described in the *Engineering Record*, of January 11th, 1913, and have been in operation for about 5 years. They provide the outlet for a reservoir with a capacity of 70 000 acre-ft., and discharge a maximum of 500 sec-ft. The outlet is a tunnel through the rock at one end of the dam, which

Mr. Wiley.

is of the earth-fill type, 142 ft. high. The tunnel is provided with sluice-gates at its upper end, which are used for drawing off the small quantity of water in the lower 50 ft. The sluice-gates are seldom used, the cylindrical gates being used almost exclusively because of their much greater ease in operation. The cylindrical gates are set at intervals of 30, 60, and 90 ft. below the water surface in a tower 100 ft. high, continued by a shaft, 50 ft. deep, to an intersection with the outlet tunnel, and 20 ft. deeper to provide a water cushion at the bottom of the shaft.

The principal feature of the outlet works of the Oakley Dam are the balanced cylindrical valves which are described very clearly by the author. These valves have given excellent service, and the writer is glad to learn that they have been as successful under the maximum head of 150 ft. at the East Canyon Creek Dam as under the head of 90 ft. at the Oakley Dam.

The building of the outlet tower inside of a shaft as a protection against ice is an attractive feature of the author's design and may be necessary in that severe climate, especially if the reservoir contains much water in the winter season. The Oakley Reservoir is usually quite low in winter, and no ill effects have been experienced from the heavy ice, although the gate-tower is in the open reservoir without protection of any kind.

The writer notes that no attempt was made to shape the abutments of the East Canyon Creek Dam to radial lines, but thinks the statement that "the line of the rock made an angle with the line of the resultant of the arch thrust equal to the full angle of repose for masonry" should be read "the normal to the line of rock", etc. It is the writer's practice to specify that the abutments for an arched dam must be stepped back on roughly radial and tangential lines, and that the average line of the points of the steps must not make an angle with the radial line greater than 30 degrees.

The frost conditions under which the concrete was placed, as described by the author, were much more severe than the writer has been accustomed to, and the placing of concrete on a frozen surface, trusting to the removal of the frost by the warmth of the new concrete, is a practice that could only be resorted to under exceptional circumstances.

The cost of the concrete, given by the author as $6.37 per cu. yd., appears to include only the hauling of the cement and the mixing and placing of the concrete, and apparently omits the cost of the cement. If this item is included, the total cost would be $8.60 per cu. yd., a very low cost for reinforced concrete for the small volume and the difficult conditions under which this work was carried out. The writer would like to ask if the costs given are the actual costs or only

Mr. Wiley. contract prices, and, if the latter, whether the relation between contract price and actual cost is known?

Mr. Bellamy. HERBERT E. BELLAMY,* M. AM. SOC. C. E. (by letter).—This paper is of the greatest interest to the writer, particularly the two points describing (1) the contraction joints, and (2) the fine clayey sand used with the concrete. It must be gratifying to the author to know that the structure is a pronounced success. In the present age, engineers all the world over are so in the habit of reading of successful works accomplished, that it is a very rare thing, indeed, to hear of a defective or faulty one. However, it is the writer's intention to refer to a dam recently constructed, which is not entirely successful, due principally to (1) faulty contraction joints, and (2) faulty sand used in the concrete. The dam in question is known as the Ridgeway Storage Dam, and is used in connection with the city water supply of Hobart, Tasmania. This dam was completed in January, 1918, and was filled to top water level in September, 1918. Figs. 10 and 11, respectively, show the plan and elevation of the dam, and the reduced levels marked thereon are, in all cases, the heights above sea level. Fig. 12 is a view of the face of the dam from the east side.

The following are the principal dimensions of the wall:

Dimensions of Dam:

Top length of west wing	293 ft. 7 in.
" " " arch	232 " 9 "
" " " east wing	203 " 6 "

Maximum Depths:

Top of arch to foundation	201 ft.
" " " " bottom of shaft	285 "
" " " " east of reservoir	100 "
East wing, maximum depth	105 "
West wing, maximum depth	103 "

Thickness:

For whole length of wall	8 ft. at top
" " " " "	6 " below coping
Arch at bottom	46 ft. 6 in.
East wing at bottom	64 ft.
West wing at bottom	58 "

Dimensions of the Reservoir:

Area of water when full	19.3 acres
Distance round edge of water	64 chains (4 224 ft.)
Maximum depth of water	95 ft.
Capacity	207 000 000 gal.

* Hobart, Tasmania.

Mr. Bellamy.

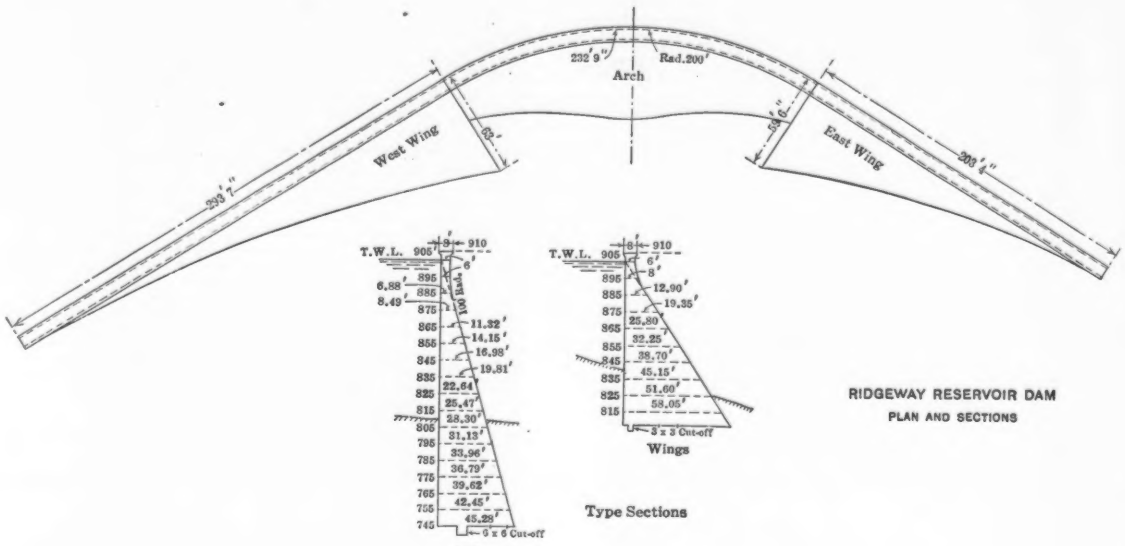

FIG. 10.

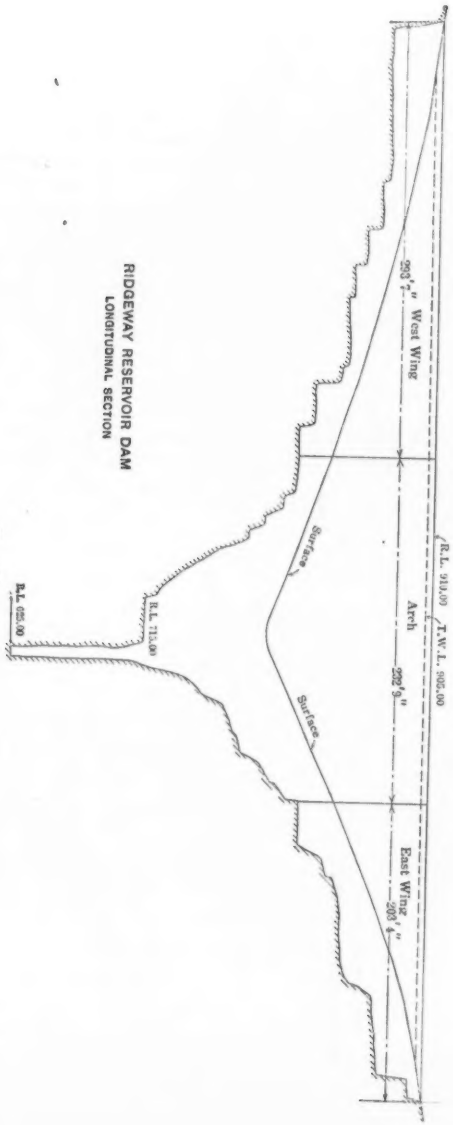
Mr. Bellamy.



RIDGEWAY RESERVOIR DAM
LONGITUDINAL SECTION

FIG. 11.

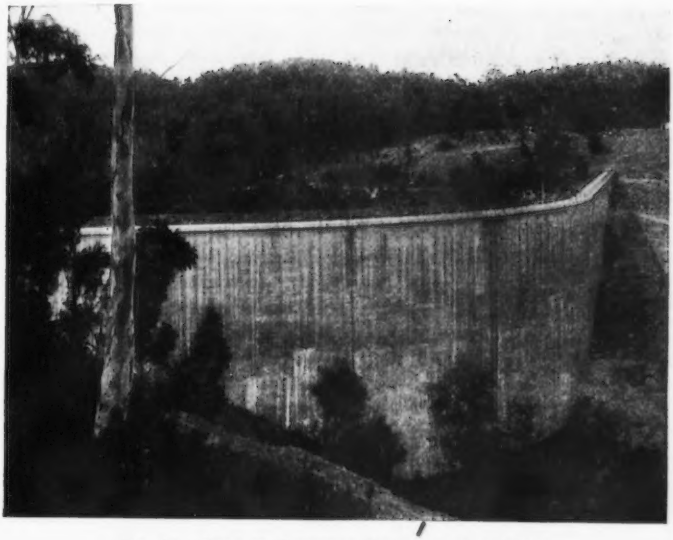


FIG. 12.—FACE OF RIDGEWAY DAM FROM EAST SIDE.

FIG. 13.—PARTING JOINT, WESTERN SIDE, RIDGEWAY DAM.

Mr. Bellamy.

The wall consists of two gravity wings with an arch between them. The wings and arch are not connected. The wall is of concrete, in varying proportions, composed of diabase (which was found on the site) and crushed sandstone. The arch is reinforced with rails, vertically and horizontally, and a reinforcement of four rails is run from end to end of the dam near the top.

The outlet works consist of a concrete tunnel more than 1 000 ft. long, and a valve tower, 108 ft. high, which is approached by a small, three-span, reinforced concrete bridge.

Between the wings and the arch of the dam wall, a 6 by 6-in. bitumen joint with sheet lead faces was carried from the ground level to a distance of 2 ft. from the top of the wall, with the object of forming a water-tight key, as shown in Fig. 14. This method, however, was absolutely ineffective, and leakages took place through these joints as the reservoir was being filled. When a depth of 30 ft. of water in the reservoir was reached, there was a great leakage through the radial joint at the junction of the arch with the eastern gravity wall, but this stopped entirely as soon as the water level had reached a height of 40 ft. No further leakage has taken place through this joint.

Regarding the joint at the junction of the arch with the western gravity wall, a leakage took place as soon as there was 30 ft. of water in the dam, and this continued to increase in intensity until the reservoir was filled to top water level 905, that is, a depth of 95 ft. The estimated quantity of water leaking through this joint was no less than 250 000 gal. per day. As this leakage was considered to be excessive, and there was apparently no hope of it taking up, the writer recommended grouting the dam under pressure, but this advice was not adopted.

Reverting to the valve tower: It was found that water commenced to leak through the wall in several places when a depth of 30 ft. was reached in the reservoir, and the leakage continued right up the wall, increasing in volume until the top water level was reached. This leakage was considered to be even more serious than that through the dam wall, and was estimated to be 300 000 gal. per day. As this leakage could not be allowed to continue, the writer recommended that the reservoir be emptied, and that an entirely new internal lining, of special concrete, 6 in. thick, be placed from the bottom to the top of the tower. This work has now been completed with entirely satisfactory results. While the reservoir was being emptied in order to effect the necessary repairs to the valve tower, very careful examinations were made by the writer of the dam wall on the up-stream side. It was found that almost the whole area of the concrete face of the wall for a depth of some 6 in. had softened and could be easily broken off. Particular attention was paid to the concrete at the parting joint on the western side. When the water level was 40 ft. from the top of the

Mr. Bellamy.

dam wall, the photograph shown in Fig 13 was taken from a boat and indicates very clearly the parting joint on the western side. The concrete at the lower horizontal crack was absolutely rotten for some 2 ft. into the wall, and it was at this point that the major leak had occurred. In order to remedy the defects, the writer had a chase cut into the wall for the full depth downward, about 18 in. wide by 12 in. deep, and this was filled with especially made concrete. In addition, he proposes to render the whole face of the dam under pressure with the cement gun.

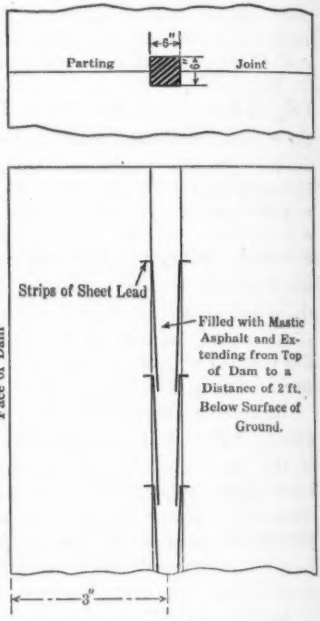

FIG. 14.

The question now leads one to consider the reason for the softening of the concrete. All the cement used throughout the works was of first-class quality and had passed all tests. The stone used was all that could be desired, but when the writer tested the disintegrated concrete, there was present a very large percentage of magnesium salts. The sand used in the concrete for the dam was obtained from a quarry almost adjoining the dam. This sandstone was taken from a small faulted block which had been carried up by the intruded greenstone, or diabase, a sill of which crowns the surrounding hills and in a hollow of which the reservoir has been constructed. A stratum of shale passes right through the sandstone which has been metamorphosed by the surrounding diabase and become impregnated by extraneous salts from the overlying decomposing rock. The writer also found several varieties of sandstone in the quarry. Analysis of the sand showed a large percentage of magnesium salts. Hence, the whole matter can be well explained as to why the concrete on the face of the wall and in the valve tower was unsatisfactory. The remedial measures which have thus been necessitated by the use of bad sand should serve to prove the absolute necessity of most thorough and searching investigations into all classes of sand likely to be used for structures; also, that short-time tests of sand and cement briquettes are not to be depended on.

Mr. Parker.

A. F. PARKER,* M. AM. SOC. C. E. (by letter).—According to reports arch dams have been built with unit stresses varying from 61 tons per sq. ft., down to 10 tons per sq. ft. They have also been built of poor materials and have departed considerably from true arch form; but, notwithstanding, there is no record of failure of an arch under water pressure. No one knows how great a loading from water pressure is required to break an arch, and, therefore, it is not known where the danger point lies or how near to it designs come.

All calculations to ascertain the strength of arch dams are based on theory and individual assumptions which vary according to the ideas of the designer. In other structures, the breaking point is often known, and thus a basis is established for intelligently applying a factor of safety, but, in all cases, facts, demonstrated by actual examples under use, finally govern. Why not frankly admit that there is no accurate knowledge of stresses in hydrostatic arches and adopt the simple formula for compressive strength in cylinders? Authorities do not agree as to the action of any stress except compressive. It will be found that, for arches not exceeding a compressive stress of, say, 25 tons per sq. ft., none of the requirements imposed by the use of numerous complicated formulas, all based on assumptions, calls for any increase of dimensions set by the simple formula.

Why not recognize precedents established by examples and adopt a factor of safety based on the actual compressive strength of the concrete used? This would be more rational than to rely on calculations based on unknown conditions which must be guessed at. From the published discussions of the subject, one can only conclude that designers have been proportioning arch dams by individual judgments; or, that is what it amounts to in the end.

There is only one rational way to ascertain, in advance of construction, the strength of concrete, and that is to fabricate actual concrete such as it is intended to use, mould it into test specimens of not less than 10 in. in diameter, so that the specimen is as truly like the concrete that will be produced on the job as it is possible to have it. Such test blocks broken in a compression machine of not less than 400 000 lb. capacity, at 30-day intervals until 6 months have elapsed, will give a basis on which to use a factor of safety.

The writer is fully convinced that the East Canyon Creek Dam is over-conservative with its unit stress of 12.5 tons per sq. ft. A procedure like the one stated above would have resulted in a unit stress of, at least, 25 tons. It is the writer's opinion that such a stress could have been safely used in designing this dam, with a corresponding saving in concrete.

So long as the rock on which the arch is built is as good as the concrete composing the arch, there is nothing to fear from water

* Ogden, Utah.

Mr. Parker.

pressure but failure under compressive stress. There is nothing to fear in an arch from uplift or pressure caused by water finding access to joints, just as long as the concrete weighs more than the water. The hydrostatic pressure is completely balanced on and resisted by the arch; this produces a definite compressive stress in the concrete of the arch.

This definite and balanced loading is wherein the arch dam differs from other arches and structures. There is no varying or live load; so it must be that calculations have a safer basis than in most cases. Ice thrust may be guarded against by vertical reinforcement, simply to distribute the ice pressure over more of the arch, above and below the ice.

The foregoing is prompted by reading Mr. Godfrey's discussion and will suffice to indicate the writer's opinion of it.

Mr. Fortier's discussion brings out some very interesting points. The development of the idea for building a dam by successive stages is well done; it must be remembered that it is in its adaptability to such practice that the arch differs from other forms of dams. The idea of using tangent gravity structures at the ends of the arch for it to abut upon where the natural contour of the canyon does not admit of using a full arch or, in other words, when the site does not admit of the use of an entire arch, to form an artificial canyon of the proper profile for an arch by means of these gravity sectioned tangent ends, is well illustrated in Mr. Bellamy's discussion. It is to be regretted that Mr. Fortier did not discuss the technical features of the dam.

Mr. Wiley's discussion gives a very interesting and instructive example of the superior qualities of arch dams. It is safe to say that in no other form than an arch can materials be made to withstand such abuse as is described in the case of the Crowley Creek Dam. It is notable that the unit stress reaches a maximum of 440 lb. per sq. in., or more than 31 tons per sq. ft. In spite of its imperfections and heavy unit stress, it withstood severe conditions of ice and floods. It adds important and convincing testimony to the increasing number of examples of abuse of workmanship and heavy loading that arch dams can stand up under.

In Mr. Wiley's comments on shaping the abutments to radial lines he states a sound principle, but, in this case, the work was carried out in a different way because of peculiar conditions that may not occur again. The design was made contemplating radial lines for all such joints and contact points.

It was an oversight that the cost of cement was not included in the cost of concrete. The figures were made up from the contractor's final estimate which did not include the cement and so it was overlooked. The prices are all contract prices, and the actual cost to the contractor of the whole or any item is not known.

Mr. Parker.

Mr. Bellamy's discussion shows an excellent example of using an arch for a dam in a canyon too wide to be filled entirely by the arch. It is an application of the principle so well stated by Mr. Fortier and shows, at a glance, the economy of cutting out the center and most costly portion of a gravity dam and substituting the cheaper arch form, cheaper because of less material in the structure and much cheaper by reason of reduced excavation for the foundation. Calculating by the simple formula a section 100 ft. below the top, it is found that the unit stress from compression is more than 22 tons per sq. ft. Also, the concrete materials are said to be poor; but still the dam does not fail. It is another argument for the idea that engineers are inclined to be too conservative in building arch dams.

Mr. Bellamy's whole discussion points to the wisdom, in designing an arch dam, of following the method of testing materials previously pointed out. Tensile tests of briquettes of cement and standard sand are only tests of the cement to show how it will behave with sand in making a mortar. The same kind of test of cement mortar made with other than standard testing sand is only a mortar test, and tensile at that. None of such tests is more than a rough, very rough, indication of what may be expected for compressive strength. The only true test is one made on large test blocks of the actual sizes and proportions of the aggregates used in the concrete.

Paper No. 1438

ON A NEW PRINCIPLE IN THE THEORY OF STRUCTURES

By George F. Swain, Past-President, Am. Soc. C. E.

With Discussion by Messrs. C. W. Hudson, Edward Godfrey, Irving P. Church, John I. Parcel, L. J. Mensch, F. E. Turneaure, G. A. Maney, William H. Burr, A. C. Janni, H. T. Eddy, William Cain, and George F. Swain.

Synopsis.

This paper explains what is believed to be a new principle in the theory of structures, which has interesting and important applications. It is known that there is little new under the sun, and it may be that this principle has been known, and published elsewhere, but the writer has not seen it, and has arrived at it independently, from his own reflections on the subject.*

1.—Deflection of a Point.

The deflection of any point, A, of any structure may be found by a well-known formula, first published in America by the writer in 1883.† This formula is

$$\Delta = \sum \frac{s\,t\,l}{E\,A} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)‡$$

* In Mohr's "Abhandlungen aus dem Gebiete der Technischen Mechanik." p. 425, this principle is hinted at, but it is not fully explained or its general applicability shown. The same thing is referred to in Grimm's book on Secondary Stresses, but incompletely elucidated.

† In a paper, entitled "On the Application of the Principle of Virtual Velocities to the Determination of the Deflection and Stresses of Frames," in the *Journal* of the Franklin Institute.

‡ If this expression causes confusion in the mind of the reader by reason of the fact that the left member is a length while the right member is apparently a force times a length, it is only necessary to remind him that in reality the left member is a length times a unit force; or, differently stated, since t is the stress due to a unit force, it may be considered as a stress due to any given force divided by that force, and, therefore, is a ratio. At any rate, the equation as it stands is perfectly correct.

in which, t = stress in any member due solely to a load of unity acting at the point the deflection of which is desired, under the given actual loads, in the direction in which said deflection is desired;

s = stress in the same member, due solely to the given actual loads;

l = length of the same member;

A = area of the same member;

E = modulus of elasticity of the same member.

This formula, as is well known, may be applied, not only to finding the deflection of a joint of a framed structure, but also to finding the deflection of any point of a beam. In the latter case, the area, A, must be replaced by an infinitesimal area, da, and the stresses, s and t, must be the stresses on such area. If the case is one of pure flexure, with no resultant axial force on any section, and if M_t is the bending moment due solely to the force unity, and M_s is the bending moment due to the actual loads, at any given section, the formula becomes

$$\Delta = \int \frac{M_s\, M_t\, d\, l}{E\, I} \qquad (2)$$

the integral being extended over the entire length.

The principle now to be explained is a similar one which affords a means of finding the rotation of the axis of any piece at any point.

2.—Angular Rotation of the Axis of a Piece at a Point. (The New Principle).

In addition to finding the deflection of any point of a structure in any given direction, it is often desired to find the angular rotation at a point, *i. e.*, the change of direction of the axis of a piece. This may be obtained by a general method analogous to that used for finding the deflection.

Let it be desired to find the angular rotation, or change of direction of the axis of a piece, at a given point, A, due to any given loads. At the given point apply only a couple the moment, M, of which equals unity, and let the corresponding angular rotation, α, at A be first determined by the method of work. (It may be thought a contradiction, or an impossibility, to apply a couple at a point, but this obviously is the same as applying two very large forces a very short distance apart,

or two forces each equal to $\frac{1}{d\,x}$ at a distance, $d\,x$, apart. This is perfectly conceivable.) The work done by the couple the moment of which is $M = 1$, if gradually applied, will obviously be $\frac{\alpha}{2}$, since the couple may be considered to consist of forces of unity a unit distance apart, and its average value is $\frac{1}{2}$. The only outer forces being this couple, the work of these outer forces is $\frac{\alpha}{2}$, and this must equal the work of the inner forces. On any bar or fiber having a uniform stress intensity throughout its area and length, due to the applied moment, $M = 1$, let r equal the total direct stress on the bar or fiber and $\Delta\, l$ its change of length. Then the equation between the work of the outer forces and that of the inner forces is

$$\frac{\alpha}{2} = \sum \frac{r}{2} \text{ (change of length), or } \alpha = \Sigma\, r \text{ (change of length).}$$

Now, as in the case of deflection, it is clear that the deformation is a purely geometrical phenomenon, and that any change of length of a bar or fiber, whatever its cause, will produce the same angular rotation at A. Hence, if for "change of length" in the above formula, which is the change of length due to $M = 1$ at A, we substitute the change of length due to any given loading, the formula will give the angular rotation at A due to the given loading, or

$$\alpha = \sum \frac{r\,s\,l}{EA} \qquad (3)$$

in which, for any given bar or fiber,

E = modulus of elasticity;
A = area;
l = length;
r = stress on the area, A, due to the couple, $M = 1$, at the given point in a given sense;
s = stress on the area, A, due to the applied loads.

The applied couple, M, may be applied with either a right-handed or left-handed direction of rotation. If α comes positive, this means that the given loads produce a rotation in the same direction as that assumed for M.

In using this equation, tension and compression, of course, should be distinguished in sign, carefully using one of these terms consistently as positive and the other as negative.

If the stresses include bending stresses, the elementary fibers, da in area and dl in length, must be taken.

The formula shows the effect of direct stresses only, shearing effects being neglected.

In applying the couple, $M = 1$, bending stresses may be produced in a bar, in addition to a direct stress in the same bar. The applied loads may produce bending or direct stresses, or both, in any bar. In such cases, for any fiber, s and r are the stresses on an area, da.

In general, if the applied loads cause in any bar at any section a direct force, T_s, and a flexural moment, M_s, the value of s will be

$$s = \left(\frac{T_s}{A} + \frac{M_s y}{I}\right) d\,a$$

and if the couple, $M = 1$, produces in the same bar and section a direct force, T_r, and a moment, M_r, the value of r will be

$$r = \left(\frac{T_r}{A} + \frac{M_r y}{I}\right) d\,a.$$

The value of the differential, $d\alpha$, therefore, will be

$$d\,\alpha = \left(\frac{T_s\,d\,a}{A} + \frac{M_s y\,d\,a}{I}\right)\left(\frac{T_r\,d\,a}{A} + \frac{M_r y\,d\,a}{I}\right)\frac{d\,l}{E\,d\,a}$$

$$= \frac{1}{E}\left[\frac{T_s\,T_r\,d\,a.d\,l}{A^2} + \frac{T_s\,M_r y.d\,a.d\,l}{A\,I} + \frac{T_r\,M_s y.d\,a.d\,l}{A\,I} + \frac{M_s\,M_r y^2.d\,a.d\,l}{I^2}\right]$$

It is supposed that every bar is straight, with one principal axis of each cross-section in the plane of the applied loads, in which plane also the couple, $M = 1$, is applied. I is the moment of inertia about the principal axis perpendicular to that plane, which, of course, passes through the center of gravity of the section, so that $\int y\,d\,a = 0$.

This differential refers to an infinitesimal length, dl, of any fiber of area, da, in any bar, and must be integrated over the cross-section, then over the length of the bar, and the sum of the results taken. The final result will easily be seen to be, if A is constant throughout the length of each bar,

$$\alpha = \Sigma\,\frac{T_s\,T_r\,l}{E\,A} + \Sigma\int_0^l \frac{M_s\,M_r\,d\,l}{E\,I} \quad \ldots\ldots\ldots\ldots (4)$$

The forces, T_r and T_s, are the direct forces acting in any bar, and are supposed to be constant throughout its length; and the moments, M_r and M_s, are the bending moments at any section of any bar. Each of the forces, s and r, in Equation (3) may, in any bar, represent a direct stress only, or flexural stress only, or both. The following results clearly follow from Equation (4):

1.—If, in any bar, either the actual load system, or the applied moment, $M = 1$, causes a direct stress only, and the other a flexural stress only, that bar may be neglected in the computation; for the value of α for that bar is zero.

2.—The flexure in any bar may be neglected unless both the actual loads and the applied moment, $M = 1$, cause flexural stress in it.

3.—The direct stress in any bar may be neglected unless both the actual loads and the applied moment, $M = 1$, cause a direct stress in it.

4.—If the case is one in which there is only flexural stress in the bars, without direct stress, the formula becomes

$$\alpha = \Sigma \int_0^l \frac{M_s M_r . d l}{E I} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

5.—If A as well as T varies along the length of any bar, the formula becomes

$$\alpha = \Sigma \int_0^l \frac{T_s T_r \, d l}{E A} + \Sigma \int_0^l \frac{M_s M_r . d l}{E I} \quad \ldots\ldots\ldots\ldots (6)$$

These principles apply in using Equation (1), to determine deflection, as in using Equation (3), to determine rotation.

3.—Illustrations of Angular Rotation.

Although this method would seldom or never be used to find the slope of a beam exposed to flexure, this case may be illustrated to show the applicability of the method.

Case I.—Slope of a Beam Fixed at One End.—Let it be desired to ascertain the slope of the free end of a beam of constant section (Fig. 1), fixed at one end and loaded at the other with a load, P. The load, P, produces on any section, distant x from the end, a moment, $M_s = -Px$. The applied couple, $M = 1$, at the free end, if acting in the sense shown, likewise produces

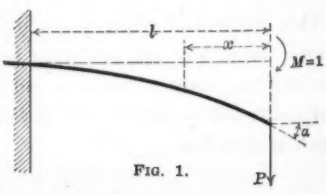

Fig. 1.

a moment at the same section, $M_r = -1$. There is no resultant direct stress on any cross-section. Hence, by Equation (4)

$$\alpha = \int_0^l \frac{P x\, dx}{E I} = \frac{P l^2}{2 E I} \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

which is the well-known value.

Again, let it be desired to find the slope at the end when a couple with moment $= M_0$ is applied at the end:

$$M_s = -M_0$$
$$M_r = -1$$
$$\text{therefore, } \alpha = \frac{M_0 l}{E I} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

This result is obtained with equal (but no greater) ease by the moment-area method.

Case II.—The Slope at the Ends of a Simple Beam Supported at Both Ends.—(a).—With a single concentrated load (Fig. 2):

Let it be desired to obtain the slope (α) at the right end of the beam of constant section shown in Fig. 2, which also shows the moment curve for M_s.

Then, clearly,

$M_s = \frac{P x (l-a)}{l}$ from left abutment to P,

$M_s = \frac{P a (l-x)}{l}$ from right abutment to P,

$M_r = \frac{x}{l}$

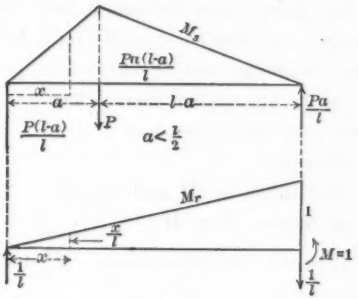

FIG. 2.

$$\text{Then } \alpha = \frac{1}{E I}\int_0^a \frac{P(l-a)}{l^2}\cdot x^2\, dx + \frac{1}{E I}\int_a^l P\,\frac{a}{l^2}\,(l x - x^2)\, dx$$

$$= \frac{P a}{6 E I l}\cdot (l^2 - a^2) \quad \ldots\ldots\ldots\ldots\ldots (9)$$

in the direction shown, that is downward to the left.

This is the simplest method of obtaining this result.

The slope at the load (α_l) may be obtained easily, by this method, by applying $M = 1$ at the load; thus (Fig. 3):

$M_s = \dfrac{P\,x\,(l-a)}{l}$ from left abutment to load,

$M_s = \dfrac{P\,a\,x_1}{l}$ from right abutment to load,

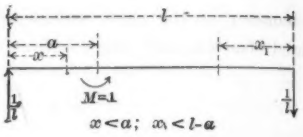

FIG. 3.

$M_r = \dfrac{x}{l}$ from left abutment to load,

$M_r = -\dfrac{x_1}{l}$ from right abutment to load,

$$\alpha_l = \frac{1}{E\,I}\int_0^a \frac{P\,x^2\,(l-a)\,d\,x}{l^2} - \frac{1}{E\,I}\int_0^{l-a} \frac{P\,a\,x_1^{\,2}\,d\,x}{l^2}$$

$$= \frac{P\,a\,(l-a)(2\,a-l)}{3\,E\,I\,l}$$

This is a negative quantity, showing that at the load the axis slopes in a contrary direction to that indicated by the applied moment, that is, it slopes downward to the right.

The point where the axis is horizontal may be easily found by this method. Let this point be distant z_0 from the right end, that is, in the longer segment; and let a moment, $M = 1$, be applied there. The slope there being zero, find $\alpha_0 = 0$, as follows:

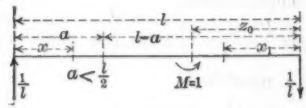

FIG. 4.

The values of M_s and M_r will be as follows (Fig. 4):

Between left end and load: $M_s = \dfrac{P\,x\,(l-a)}{l}$

$$M_r = \frac{x}{l}$$

Between right end and z_0: $M_s = \dfrac{P\,a\,x_1}{l}$

$$M_r = -\frac{x_1}{l}$$

Between z_0 and load: $M_s = \dfrac{P\,a\,x_1}{l}$

$$M_r = -\frac{x_1}{l} + 1$$

$$E\,I\,\alpha_0 = 0 = \int_0^a \frac{P\,x^2\,(l-a)}{l^2}\,dx - \int_0^{z_0} \frac{P\,a\,x_1^2}{l^2}\,dx_1 - \int_{z_0}^{l-a} \frac{P\,a\,x_1^2}{l^2}\,dx_1$$

$$+ \int_{z_0}^{l-a} \frac{P\,a\,x_1}{l}\,dx_1, \text{ or } z_0 = \sqrt{\frac{l^2-a^2}{3}}$$

(*b*).—To find slope at the right end due to a moment, M_1, at the left end, causing compression in the top fibers (Fig. 5):

$$M_s = \frac{M_1\,(l-x)}{l}$$

$$M_r = \frac{x}{l}$$

$$\alpha = \int_0^l \frac{M_1\,x\,(l-x)\,dx}{l^2\,E\,I}$$

$$= \frac{M_1\,l}{6\,E\,I} \cdots\cdots\cdots\cdots (10)$$

acting in the direction of the moment, $M = 1$, or downward to the left.

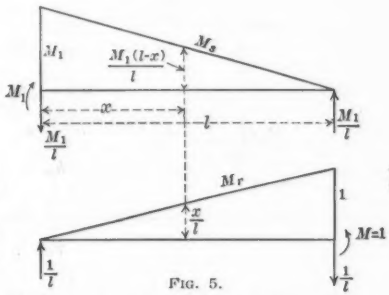

FIG. 5.

(*c*).—To find the slope at the right end due to a moment, M_2, at the right end, causing compression in the top fibers (Fig. 6):

$$M_s = \frac{M_2\,x}{l}$$

$M_r = \frac{x}{l}$, as before,

$$\alpha = \int_0^l \frac{M_2\,x^2\,dx}{l^2\,E\,I} = \frac{M_2\,l}{3\,E\,I} \cdot (11)$$

downward to the left.

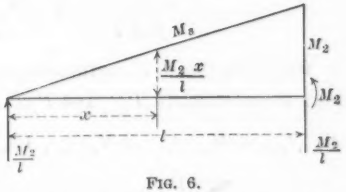

FIG. 6.

Case III.—The Continuous Girder.—Theorem of Three Moments.—This principle affords what the writer believes to be the simplest method of demonstrating the Theorem of Three Moments, which follows immediately from Case II. See Fig. 7.

Fig. 7 shows two consecutive spans of a continuous girder, l_{n-1} and l_n, each with a single concentrated load in it. The span, l_{n-1}, is exposed to the action of its load, and to moments, M_{n-1} and M_n, at the supports. In addition, the level of the support, n-1, may be lowered so that it is h_{n-1} above a base line, while the support, n, is h_n above that base. The

slope at n, in the direction downward to the left, resulting from P_{n-1}, M_{n-1}, M_n, and the change of level of supports will be, from Equations (9), (10), and (11):

$$\alpha_n = \frac{P_{n-1}\, a_{n-1}\,(l^2_{n-1} - a^2_{n-1})}{6\,E\,I\,l_{n-1}} + \frac{M_{n-1}\,l_{n-1}}{6\,E\,I} + \frac{M_n\,l_{n-1}}{3\,E\,I} + \frac{h_n - h_{n-1}}{l_{n-1}} \cdot \quad (12)$$

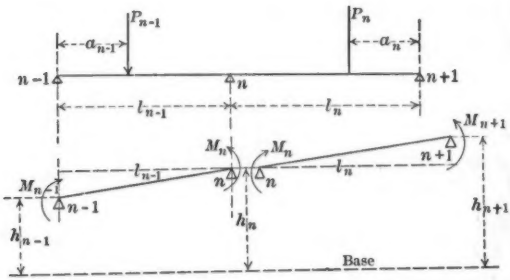

FIG. 7.

The span, l_n, is likewise exposed to the action of P_n, and of moments, M_n and M_{n+1}, and also the support, $n+1$, may be raised above n. Under these conditions, the slope at n, in a direction downward to the right, will be

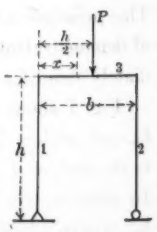
$$\alpha'_n = \frac{P_n\, a_n\,(l_n^2 - a_n^2)}{6\,E\,I\,l_n} + \frac{M_{n+1}\,l_n}{6\,E\,I} + \frac{M_n\,l_n}{3\,E\,I} - \frac{h_{n+1} - h_n}{l_n} \ldots . (13)$$

But, if the beam is continuous, $\alpha_n = -\alpha_n'$, or $\alpha_n + \alpha_n' = 0$; hence, for a series of loads, P_{n-1} and P_n,

$$M_{n-1}\,l_{n-1} + M_{n+1}\,l_n + 2\,M_n\,(l_{n-1} + l_n) = 6\,E\,I\left(\frac{h_{n+1} - h_n}{l_n} - \frac{h_n - h_{n-1}}{l_{n-1}}\right)$$
$$- \sum \frac{P_n\, a_n}{l_n}\,(l_n^2 - a_n^2) - \sum \frac{P_{n-1}\, a_{n-1}}{l_{n-1}}\,(l^2_{n-1} - a_{n-1})^2 \ldots (14)$$

which is the most general form of the Theorem of Three Moments.

Case IV.—Slope (α) at the Foot of One Post of a Rigid Rectangular Bent Supported on Pins, and One Pin on Rollers.—In Fig. 8, owing to the rollers, there are no horizontal reactions at the supports. By symmetry, each vertical reaction is $\frac{P}{2}$.



The applied load, P, produces, in each post, merely a compression, $\frac{P}{2}$; and, in the upper piece, flexure, with a triangular moment diagram having a center ordinate, $\frac{P\,b}{4}$.

The applied couple, $M = 1$, produces (Fig. 9) in the left post a compression of $\frac{1}{b}$; and in the right post a tension of $\frac{1}{b}$, together with a uniform bending moment of $M = 1$ at each point, and in the upper piece a bending moment causing compression in the top fibers, and varying uniformly from zero at the left support to 1 at the right support.

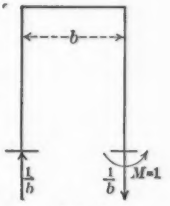


FIG. 9.

From Equation (2) we find, numbering the parts as shown,

$$\alpha = \frac{P\,h}{2\,b\,E_1\,A_1} - \frac{P\,h}{2\,b\,E_2\,A_2} + \int_0^{\frac{b}{2}} \frac{P\,x^2\,d\,x}{2\,b\,E_3\,I_3} + \int_{\frac{b}{2}}^{b} \frac{P}{2}\,(b - x)\,\frac{x\,d\,x}{b\,E_3\,I_3}$$

$$= \frac{P\,h}{2\,b\,E_1\,A_1} - \frac{P\,h}{2\,b\,E_2\,A_2} + \frac{P\,b^2}{16\,E_3\,I_3}$$

If, as would generally be the case, $E_1 = E_2 = E_3 = E$, and $A_1 = A_2$,

$$\alpha = \frac{P\,b^2}{16\,E\,I_3}$$

or the same as at the end of the upper beam loaded at the center, as it obviously should be.

Case V.—A King-Post Truss.—Let it be required (Fig. 10) to find the angular rotation (α) of the end of the top chord, all joints being supposed to be connected by frictionless pins. The load, P, is at the center.

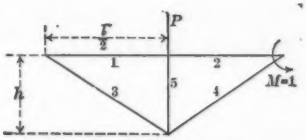

FIG. 10.

For the bars numbered, the values of l, r, and s, are given in Table 1.

The couple, $M = 1$, in the direction shown, causes an upward reaction of $\frac{2}{l}$ on Bar 2 at the left end, and an equal downward reaction at its right end, in other words, a compression on Bar 5 equal to $\frac{2}{l}$, and an upward force of $\frac{2}{l}$ on the end pin at the abutment. This com-

TABLE 1.

Bar.	Length.	Stress, r, due to $M = 1$ at right end of 2.	Stress, S, due to the load, P.
1	$\frac{l}{2}$	$-\frac{1}{2h}$	$-\frac{Pl}{4h}$
2	$\frac{l}{2}$	$-\frac{1}{2h}$ + flexure	$-\frac{Pl}{4h}$
3	$\sqrt{h^2+\frac{l^2}{4}}$	$\frac{1}{lh}\sqrt{h^2+\frac{l^2}{4}}$	$\frac{P}{2h}\sqrt{h^2+\frac{l^2}{4}}$
4	$\sqrt{h^2+\frac{l^2}{4}}$	$\frac{1}{lh}\sqrt{h^2+\frac{l^2}{4}}$	$\frac{P}{2h}\sqrt{h^2+\frac{l^2}{4}}$
5	h	$-\frac{2}{l}$	$-P$

pression on Bar 5 causes tension in Bars 3 and 4 and a downward pull on the pin at the right end of Bar 2 equal to $\frac{1}{l}$, leaving a resultant upward force of $\frac{1}{l}$ on the pin, which must be balanced by a downward reaction exerted by the abutment, as must clearly be the case to balance $M = 1$, independent of any internal stresses. Similarly, the upward reaction at the left abutment is $\frac{1}{l}$.

By the second principle, explained in Paragraph 2, the flexure in Bar 2 does not enter into the equation for slope; hence, the material being uniform, and each bar of constant section and uniform material, if $A_1 = A_2$, and $A_3 = A_4$,

$$E.\alpha = \frac{P\,l^2}{8\,h^2\,A_1} + \frac{P}{l\,h^2\,A_3}\left(\frac{l^2}{4}+h^2\right)^{\frac{3}{2}} + \frac{2\,P\,h}{l\,A_5} \quad \ldots\ldots(15)$$

This may be checked by the usual method, which would be to find first the deflection, Δ, of the top of 5, by Table 2.

$$\Delta = \sum \frac{s\,t\,l}{E\,A} = \frac{1}{E}\left[\frac{P\,l^3}{16\,h^2\,A_1} + \frac{P}{2\,h^2\,A_3}\left(\frac{l^2}{4}+h^2\right)^{\frac{3}{2}} + \frac{Ph}{A_5}\right]$$

$\alpha = \frac{2\,\Delta}{l}$, which is the same as Equation (15).

Case VI.—A Framed Bent with Columns Rigidly Fixed at the Bottom.—Consider the bent shown in Fig. 11, and suppose all joints hinged except where the knee-braces meet the columns. The structure

is then statically determined as regards the inner forces, but not as regards the outer forces. Suppose that it is imagined to be made determined by having each column supported on a frictionless pin, and one of them (the right-hand one) on a roller. Under these circumstances, the structure will be entirely statically determined, but the distance between the feet of the columns will change (increase generally), and the axis of the columns at the bottom will rotate. To bring the structure into the condition in which it actually is, apply a horizontal inward force, H_0, at the bottom of the right-hand column, a couple with left-handed moment, M_1, at the bottom of the right-hand column, and a couple with right-hand moment, M_2, at the bottom of the left-hand column. If these three quantities, H_0, M_1, and M_2, can be found, the problem is solved. The conditions which determine them are that the resultant change of span is zero, and that the resultant rotation of the bottom of each column is zero. It remains to formulate these conditions.

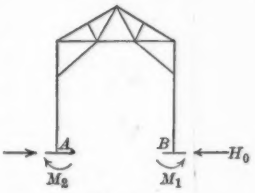

FIG. 11.

In any bar (or fiber, if there is flexure) of the statically determined structure, let

S_0 = stress due to the actual loads,
t = " " " an outward force of unity at B,
r_1 = " " " a right-handed moment of unity at B,
r_2 = " " " " left-handed " " " " A,

Then the actual stress in that bar or fiber will be

$$S = S_0 - H_0 t - M_1 r_1 - M_2 r_2$$

The outward deflection of B, which is zero, will be

$$\Delta = 0 = \sum \frac{s\,t\,l}{E\,A} = \sum \frac{s_0\,t\,l}{E\,A} - H_0 \sum \frac{t^2\,l}{E\,A} - M_1 \sum \frac{r_1\,t\,l}{E\,A} - M_2 \sum \frac{r_2\,t\,l}{E\,A} \quad \ldots\ldots\ldots\ldots (16)$$

The rotation of B in a right-handed direction, which is zero, will be

$$\alpha_1 = 0 = \sum \frac{s\,r_1\,l}{E\,A} = \sum \frac{s_0\,r_1\,l}{E\,A} - H_0 \sum \frac{t\,r_1\,l}{E\,A} - M_1 \sum \frac{r_1^2\,l}{E\,A} - M_2 \sum \frac{r_1\,r_2\,l}{E\,A} \quad \ldots\ldots\ldots\ldots (17)$$

TABLE 2.

Bar.	Length.	Stress, t, due to load 1 at top of Bar 5.	Stress, s, due to load, P, at top of Bar 5.
1	$\frac{l}{2}$	$-\frac{l}{4h}$	$-\frac{P}{4h}$
2	$\frac{l}{2}$	$-\frac{l}{4h}$	$-\frac{Pl}{4h}$
3	$\sqrt{h^2+\frac{l^2}{4}}$	$\frac{1}{2h}\sqrt{h^2+\frac{l^2}{4}}$	$\frac{P}{2h}\sqrt{h^2+\frac{l^2}{4}}$
4	$\sqrt{h^2+\frac{l^2}{4}}$	$\frac{1}{2h}\sqrt{h^2+\frac{l^2}{4}}$	$\frac{P}{2h}\sqrt{h^2+\frac{l^2}{4}}$
5	h	-1	$-P$

The rotation of A in a left-handed direction, which is zero, will be

$$\alpha_2 = 0 = \sum \frac{s\, r_2\, l}{E\, A} = \sum \frac{s_0\, r_2\, l}{E\, A} - H_0 \sum \frac{t\, r_2\, l}{E\, A} - M_1 \sum \frac{r_1\, r_2\, l}{E\, A} - M_2 \sum \frac{r_2^{\,2}\, l}{E\, A} \quad \ldots\ldots(18)$$

If the material is uniform throughout, E may be cancelled.

All the stresses indicated in these equations may be found by statics, and tabulated, and the summations found. Designating the sums by letters, a, b, c, d, e, f, g, h, k, the equations may be written

$$a = H_0 b + M_1 c + M_2 d \quad \ldots\ldots(16)$$
$$e = H_0 c + M_1 f + M_2 g \quad \ldots\ldots(17)$$
$$h = H_0 d + M_1 g + M_2 k \quad \ldots\ldots(18)$$

in which all the constants are known, and the problem is to find H_0, M_1, and M_2.

The solution gives the following values:

$$M_1 = \frac{(a\,d - h\,b)\,(d\,c - b\,g) - (a\,c - e\,b)\,(d^2 - k\,b)}{(c\,d - g\,b)^2 - (c^2 - f\,b)\,(d^2 - k\,b)} \quad \ldots\ldots(19)$$

$$M_2 = \frac{(a\,c - e\,b)\,(d\,c - b\,g) - (a\,d - h\,b)\,(c^2 - f\,b)}{(c\,d - g\,b)^2 - (c^2 - f\,b)\,(d^2 - k\,b)} \quad \ldots\ldots(20)$$

$$H_0 = \frac{a - M_1\, c - M_2\, d}{b} \quad \ldots\ldots(21)$$

These three equations completely solve this case. In any actual case, the values in these equations will be numerical, and can easily be substituted. To obtain a general value of M_1, M_2, and H_0, in any special

case, by this method, is possible, but is long and complicated, and other methods are very likely to be shorter and more easily visualized.

In this, as in all statically undetermined cases, it is necessary, in designing, first to make some assumptions which will make the structure statically determined, design the sections on this assumption, and then use the foregoing equations for a more exact design, repeating the process if necessary.

In the present case, if the applied loads and the outline of the structure are symmetrical about a vertical center line, it is easily seen that $e = h$, $c = d$, $f = k$, and that $M_1 = M_2$, hence

$$M_1 = M_2 = \frac{ac - eb}{2c^2 - gh - fb} \quad \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

$$H_0 = \frac{2ec - a(g + f)}{2c^2 - b(g + f)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

The point of inflection in either post, in this case, will be at a height above the base

$$h_0 = \frac{M_1}{H_0} = \frac{ac - eb}{2ec - a(g + f)}.$$

In obtaining any of the sums required, the principles relating to combinations of direct stress with flexure, explained in Paragraph 2, apply.

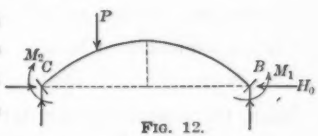

FIG. 12.

Case VII.—The Arch Without Hinges.—In this case (Fig. 12) there are three equations to be supplied by elastic conditions, namely:

(1).—The change of span = 0,
(2).— " " " slope at $B = 0$,
(3).— " " " " " $C = 0$.

Suppose, first, the arch to be statically determined as regards the outer forces, by being supported on frictionless pins, and B on rollers. On any bar (or fiber, if there is flexure) of the statically determined structure, let

S_0 = stress due to the actual loads;
t = " " " an outward load of unity at B;
r_1 = " " " a right-handed moment of unity at B;
r_2 = " " " " left-handed " " " " C.

Let the actual thrust (H_0), the moment at B (M_1), and the moment at C (M_2), be assumed to act as shown. Then the equations of Case VI apply here, and the solution is given by Equations (19), (20), and (21), all the quantities in those equations being easily found by statics.

The further discussion and illustration of these results are interesting and valuable, but need not be given here, as the purpose is merely to explain the new principle which, if not first stated, is believed to be first explained, in this paper.

It is not the intention here to do more than explain the principle and illustrate its application. The reader who thoroughly grasps it will find that it may be applied usefully in many ways.

Case VIII.—Secondary Stresses.—The principle herein explained may be applied to the determination of the secondary stresses in framed structures, in the following manner:

Let the structure be a frame with assumed frictionless connections, and with bars arranged so as to be statically determined as regards the inner forces. The secondary stresses arise from the fact that, if the joints are riveted, they are far from frictionless, so that unknown bending moments are introduced at the ends of the bars. There is such a bending moment at each end of each bar.

Let n = number of bars,
m = " " joints.

Then, the structure being statically determined with regard to the inner forces, the condition is fulfilled

$$n = 2m - 3$$

Now, as regards the secondary stresses, the only unknown quantities are the bending moments at the ends of the bars, so that

$$x = \text{number of unknown quantities} = 2n.$$

The conditions from which these unknown quantities may be found are, that with rigid connections the angles between the bars at any given joint are unchanged, or, in other words, that the rotation of every bar meeting at a joint is the same.

At all but four of the joints there will be, in general, four bars meeting, if the frame is a simple triangular frame, so that at each such joint there will be three equations. At two joints there will be three bars meeting, and two equations; and at two joints there will be two bars meeting, and one equation. In addition, there is the condi-

tion at each joint that the algebraic sum of the moments at the ends of the bars meeting there must be zero. Hence, the number of equations will be

$$3\ (m - 4) + 4 + 2 + m = 4m - 6 = 2n$$

so that there are just equations enough to determine the unknown quantities.

The foregoing holds thus far for any frame composed of simple triangles like a Warren truss, in Fig. 13, but not for such a truss with secondary bars; but, if the method of developing the truss with secondary bars is considered, the principle will be found to be true for such a truss also.

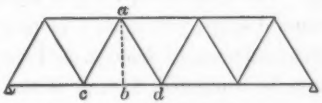

FIG. 13.

Consider the simple Warren truss, as shown in Fig. 13. If, now, it is desired to add a secondary bar, *ab*, by connecting an existing joint, *a*, with some point, *b*, in another bar, *cd*, one new joint is added (*b*), and two new bars (*ab* and *cb* or *bd*). For the original truss

$$n = 2m - 3.$$

If m_1 secondary bars are added, such as *ab*, there will be $2m_1$ new bars added, so that

$$\begin{aligned} n_0 = \text{number of bars} &= n + 2\ m_1 = 2\ m - 3 \\ &+ 2\ m_1 = 2\ (m + m_1) - 3 \\ m_0 = \text{number of joints} &= m + m_1 \end{aligned}$$

and, as before, $n_0 = 2\ m_0 - 3$, or the structure is still statically determined.

As regards secondary stresses, the number of conditions in the original truss was $4\ m - 6$. For each secondary bar added, there is a joint, *b*, added, at which there are three bars meeting, and two conditions, hence there will be $2\ m_1$ additional conditions if m_1 secondary bars are added. Also, at each of these joints, *b*, $\Sigma M = 0$, which gives m_1 more conditions; also, at each joint, *a*, there is one more bar and hence one more condition, which gives m_1 more conditions. Hence, the addition of m_1 secondary bars gives $4\ m_1$ additional conditions, making the total number of conditions $4\ m - 6 + 4\ m_1$. The number of bars will be $n + 2\ m_1$, and the number of unknown quantities will be

$$2\ (n + 2\ m_1) = 4\ m - 6 + 4\ m_1$$

or the same as the number of conditions.

All the stresses due to the moments at the ends of the bars may be easily computed by statics, and the resulting numerical equations may be solved, in any given case, though general formulas would be difficult to deduce, and are unnecessary.

The effect of eccentricity of the connections may be taken account of by the same method. The stress in any bar is assumed to act in the line joining the ideal joints of the truss. If this line is not through the center of gravity of the cross-section of the bar, it causes a moment at each end, which is a part of the total moment at that end.

In the same way, the effect of pin connections may be taken account of. The friction on the pin when the bar tends to rotate on it as the truss deflects, will cause a moment at the end of the bar, depending on the coefficient of friction and the diameter of the pin. The structure may be computed, first, as if the joints were rigid, and the moment at the end of the bar found. If this moment proves to be less than the frictional moment, the bar will then be actually rigidly fixed at the end, notwithstanding the pin connection. If the moment as found proves to be greater than the frictional moment, the latter is to be taken as the true moment, and the results throughout the truss modified accordingly.

DISCUSSION

Mr. Hudson.

C. W. Hudson,* M. Am. Soc. C. E. (by letter).—The writer has read this paper with great interest and has verified the derivations of the numbered equations. The general statement involved in Equation (3) he has not seen before, and the same may be said of Equation (4). In the short time in which the writer has studied the possibility of the application of Equation (4) to determine the angular rotation of any normal section of a bar, he is unable to see that it has any advantage, from the labor-saving standpoint, in shortening or abbreviating such calculations. Equations (1) and (2) and the further well-known equation, $\Delta \alpha = \int \frac{M\, d\, s}{E\, I}$, furnish the basis for the solution of all the problems which may be solved by Equation (4), and it is believed by the writer that the resulting solution of many problems would be the same, term for term, in either case. As the author states, it is often desired to find the angular rotation of the axis at a definite point of a bar subject to flexure. This, of course, is the same in direction and amount as the angular rotation of a section normal to the axis at the point. For about 16 years the writer has been using Equation (2) to determine the angular rotation of certain planes for which the author shows the application of Equation (5). If the auxiliary force of unity, imagined in the application of the general Equation (2), is considered as applied parallel to the axis of a straight bar at any cross-section of the bar and at a unit's distance from the axis, the deflection at the point of application of the unit force, divided by unity, is the angular rotation of the cross-section, in radians. As illustrations:

Equations (7) and (8) of Case I are seen to follow directly from Equation (2), with the aid of Fig. 14.

For the various equations derived for Case II: Equation (9) will be seen to follow directly from Equation (2), in connection with Fig. 15.

The slope at the load (α_l) is obtained from Equation (2), in connection with Fig. 16.

The point where the axis is horizontal may be found from Equation (2), in conjunction with Fig. 17.

The slope at the right end, given by Equation (10), due to the moment, M, at the left end causing compression in the top fibers of Fig. 5, may be found from Equation (2) and the data of Fig. 18.

The slope at the right end, given by Equation (11), due to a moment, M_2, at the right end causing compression in the top fibers of Fig. 6, may be found from Equation (2) in conjunction with Fig. 18.

The results obtained by the use of Equation (2) are identical with those obtained by the use of Equation (5) in each of the foregoing, and it would appear that Equation 5 is only a special case of Equation (2).

* New York City.

Mr. Hudson.

The author's derivation of the theorem of three moments under Case III follows directly from the relations established for the various subdivisions of Case II, and, therefore, may be said to be derived wholly by the use of Equation (2). There are numerous forms of the three-moment equation. In the latter part of 1916, the writer derived, and published,* the following well known three-moment equation as well as several other three-moment equations, by means of the angular rotation of the vertical plane section over any intermediate support of a continuous beam. The derivations referred to and the following are from Equation (2). Let Fig. 19 represent any two adjacent spans of a continuous beam resting on level supports. Let the nature of the supports be such that the beam is without restraint in a longitudinal direction.

Let Fig. 20 show the left span of Fig. 19, on which the forces and moments shown are those existing when this span is acting as a part of the whole beam. In order to find the angular motion of the end planes of this span of the beam, the auxiliary load of unity will be considered to be applied at a unit's distance from the axis.

For determining the angular rotation of the left end, the auxiliary force of unity, and the reactions produced by it, are shown in Fig. 21.

The clockwise motion of the left end is:

$$\alpha_{2l} = \int_0^{l_2} -M_2 \left(1 - \frac{x}{l_2}\right) \frac{d\,x}{E\,I_2} + \int_0^{l_2} -\frac{(M_3 - M_2)}{l_2}\, x \left(1 - \frac{x}{l_2}\right) \frac{d\,x}{E\,I_2}$$

$$+ \int_0^{l_2} P_2\,(1 - k_2)\, x \left(1 - \frac{x}{l_2}\right) \frac{d\,x}{E\,I_2}$$

$$+ \int_{k_2 l_2}^{l_2} -P_2\,(x - k_2\,l_2) \left(1 - \frac{x}{l_2}\right) \frac{d\,x}{E\,I_2}$$

$$= \frac{M_2}{E}\left[-\int_0^{l_2} \frac{d\,x}{I_2} + \int_0^{l_2} \frac{2\,x\,d\,x}{I_2\,l_2} - \int_0^{l_2} \frac{x^2\,d\,x}{I_2\,l_2^2}\right] + \frac{M_3}{E}\left[-\int_0^{l_2} \frac{x\,d\,x}{I_2\,l_2}\right.$$

$$\left. + \int_0^{l_2} \frac{x^2\,d\,x}{I_2\,l_2^2}\right] + \frac{P_2}{E}\left[+\int_0^{k_2 l_2} \frac{x\,d\,x}{I_2} + k_2 \int_0^{k_2 l_2} \frac{x\,d\,x}{I_2} - \frac{1}{l_2}\int_0^{k_2 l_2} \frac{x^2\,d\,x}{I_2}\right.$$

$$\left. + k_2\,l_2 \int_{k_2 l_2}^{l_2} \frac{d\,x}{I_2} - 2\,k_2 \int_0^{l_2} \frac{x\,d\,x}{I_2} + \frac{k_2}{l_2}\int_0^{l_2} \frac{x^2\,d\,x}{I_2}\right] \ldots\ldots (D)$$

Fig. 22 shows the auxiliary force of unity, and its reactions, necessary to determine the clockwise motion of the right-end plane which is, in the same manner as before:

$$\alpha_{2r} = \frac{M_2}{E}\left[\int_0^{l_2} \frac{x\,d\,x}{I_2\,l_2} - \int_0^{l_2} \frac{x^2\,d\,x}{I_2\,l_2^2}\right] + \frac{M_3}{E}\int_0^{l_2} \frac{x^2\,d\,x}{I_2\,l_2^2} + \frac{P_2}{E}$$

$$\left[-\frac{1}{l_2}\int_0^{k_2 l_2} \frac{x^2\,d\,x}{I_2} + \frac{k_2}{l_2}\int_0^{l_2} \frac{x^2\,d\,x}{I_2} - k_2 \int_{k_2 l_2}^{l_2} \frac{x\,d\,x}{I_2}\right] \ldots\ldots (E)$$

* In the *Polytechnic Engineer* for 1917.

Mr. Hudson.

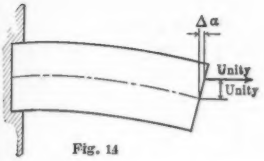

Fig. 14

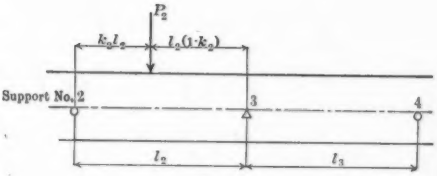

Fig. 19

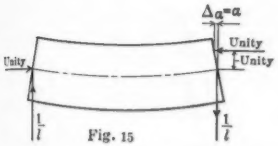

Fig. 15

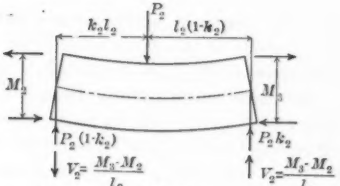

Fig. 20

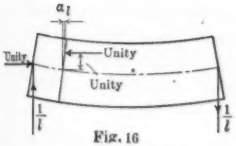

Fig. 16

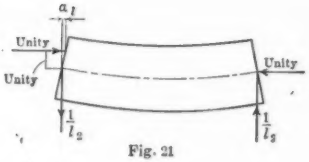

Fig. 21

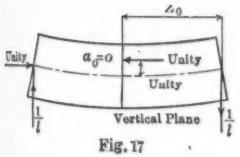

Fig. 17

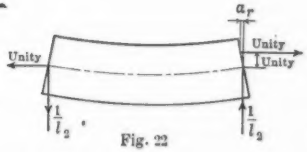

Fig. 22

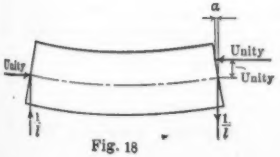

Fig. 18

Mr. Hudson.

For the right-hand span of Fig. 19, the angular changes of the end planes under the same assumptions as for the left span are:

$$\alpha_{3l} = \frac{M_3}{E}\left[-\int_0^{l_3}\frac{d\,x}{I_3} + \int_0^{l_3}\frac{2\,x\,d\,x}{I_3\,l_3} - \int_0^{l_3}\frac{x^2\,d\,x}{I_3\,l_3^2}\right] + \frac{M_4}{E}\left[-\int_0^{l_3}\frac{x\,d\,x}{I_3\,l_3}\right.$$
$$\left. + \int_0^{l_3}\frac{x^2\,d\,x}{I_3\,l_3^2}\right] + \frac{P_3}{E}\left[+\int_0^{k_3\,l_3}\frac{x\,d\,x}{I_3} + k_3\int_0^{k_3\,l_3}\frac{x\,d\,x}{I_3} - \frac{1}{l_3}\int_0^{k_3\,l_3}\right.$$
$$\left.\frac{x^2\,d\,x}{I_3} + k_3\,l_3\int_0^{l_3}\frac{d\,x}{I_3} - 2\,k_3\int_0^{l_3}\frac{x\,d\,x}{I_3} + \frac{k_3}{l_3}\int_0^{l_3}\frac{x^2\,d\,x}{I_3}\right]\ldots(F)$$

and $$\alpha_{3r} = \frac{M_3}{E}\left[\int_0^{l_3}\frac{x\,d\,x}{I_3\,l_3} - \int_0^{l_3}\frac{x^2\,d\,x}{I_3\,l_3^2}\right] + \frac{M_4}{E}\int_0^{l_3}\frac{x\,d\,x}{I_3\,l_3^2} + \frac{P_3}{E}$$
$$\left[-\frac{1}{l_3}\int_0^{k_3\,l_3}\frac{x^2\,d\,x}{I_3} + \frac{k_3}{l_3}\int_0^{l_3}\frac{x^2\,d\,x}{I_3} - \frac{k_3}{l_3}\int_{k_3\,l_3}^{l_3}\frac{x\,d\,x}{I_3}\right].....(G)$$

When the beam is acting as a whole, α_{2r} equals α_{3l}, as they are angular rotations of the same plane; therefore, we may write the right half of Equation (E) equal to the right half of Equation (F). Before writing the equation it should be noted that M_2, M_3, and M_4, have been used, as shown in Fig. 20, as negative moments, hence their values as determined from any combination of the foregoing equations would be positive. Therefore, it will be best to change the signs of the moments over the supports to make them agree with the general convention. By doing this, there results the following equation of three moments:

$$M_2\left[-\int_0^{l_2}\frac{x\,d\,x}{I_2\,l_2} + \int_0^{l_2}\frac{x^2\,d\,x}{I_2\,l_2}\right] - M_3\int_0^{l_2}\frac{x^2\,d\,x}{I_2\,l_2^2} + M_3\left[-\int_0^{l_3}\frac{d\,x}{I_3}\right.$$
$$\left. + \int_0^{l_3}\frac{2\,x\,d\,x}{I_3\,l_3} - \int_0^{l_3}\frac{x^2\,d\,x}{I_3\,l_3^2}\right] + M_4\left[-\int_0^{l_3}\frac{x\,d\,x}{I_3\,l_3} + \int_0^{l_3}\frac{x^2\,d\,x}{I_3\,l_3^2}\right] =$$
$$-P_2\left[-\frac{1}{l_2}\int_0^{k_2\,l_2}\frac{x^2\,d\,x}{I_2} + \frac{k_2}{l_2}\int_0^{l_2}\frac{x^2\,d\,x}{I_2} - k_2\int_{k_2\,l_2}^{l_2}\frac{x\,d\,x}{I_2}\right] + P_3$$
$$\left[\int_0^{k_3\,l_3}\frac{x\,d\,x}{I_3} + k_3\int_0^{k_3\,l_3}\frac{x^2\,d\,x}{I_3} + k_3\,l_3\int_{k_3\,l_3}^{l_3}\frac{d\,x}{I_3} - 2\,k_3\int_0^{l_3}\frac{x\,d\,x}{I_3}\right.$$
$$\left. + \frac{k_3}{l_3}\int_0^{l_3}\frac{x^2\,d\,x}{I_3}\right].....(H)$$

Equation (H) may be used to design or investigate continuous girders having a varying moment of inertia. A somewhat simpler form of Equation (H) may be derived by measuring x and k from the left end of the left span and the right end of the right span of the two spans adjacent to any support. The differences in elevation of the supports may readily be included in the foregoing, provided they are small, as it is entirely a matter of geometry.

Case IV is in reality only a repetition of Case II.

Mr. Hudson.

Case V is more readily solved by Equation (1) than by Equation (4), as the author shows.

With respect to the remaining cases, suggested for illustration by the author, the writer believes, that Equations (1) and (2) will give simpler solutions than Equation (4), with the possible exception of Case VIII. For the latter, the value of the method can only be determined by considerable investigation, and this the writer has not made.

Mr. Godfrey.

EDWARD GODFREY,* M. AM. SOC. C. E. (by letter).—The formula given in Equation (1) is familiarly known as the "Sigma $p\ u\ l$ over E" formula, though that equation is not in the same shape as this easily remembered form. In the familiar form it is

$$\Delta = \Sigma \frac{p\ u\ l}{E}$$

where Δ is the deflection of any point in a frame in a given direction;

p is the stress in any member of the frame due to a load of 1 lb. in that same direction and applied at the same point;

u is the unit stress in the member under its stress;

l is the length of the member;

and E is the modulus of elasticity.

This is a useful equation and the form just given is a simple one to remember and apply. The writer has used it in dealing with drawbridges and hingeless arches, and it is needed for such indeterminate cases.

The author's new formula may also be found useful for indeterminate cases. It might be suggested that it be simplified to the form

$$\alpha = \Sigma \frac{r\ u\ l}{E}$$

where α is the angular rotation in a frame in any point in a given direction;

r is the stress in any member of the frame due to a couple of unity, applied at the point in question, that will tend to give rotation in that same direction;

and the other values are as before.

This could be called the "Sigma $r\ u\ l$ over E" formula.

The writer believes there is an error in Equation (7) in which the inclination at the end of a cantilever beam is given as $\frac{P\ l^2}{E\ I}$, and that it should be $\frac{P\ l^2}{2\ E\ I}$.

* Pittsburgh, Pa.

Mr. Godfrey.

Although the writer does not question the correctness of the formulas nor the possibilities of their usefulness in a limited way, he thinks that their application to a king-post truss and framed bents, and to secondary stresses from such causes as rotation of members on the pins due to deflection or to rigidity of riveted connections, although interesting as studies in what might be called pure applied mathematics, have no place in practical engineering.

The reason for this is twofold, and both phases deserve consideration and emphasis. Stating the reasons briefly: (1) Perhaps not one engineer in fifty doing practical designing could follow this paper or apply it in a practical design; (2) There is no reason on earth why it should be applied in a practical design.

Taking these up separately: Is there any reason for not simplifying mathematics so that the average designer can understand and apply it? The writer does not hesitate to state that, if it is a matter of the designing of ordinary construction, the design should be simplified down to the last degree. There are some structures, such as suspension bridges and fixed-ended arches, that come up only once in a long time, and these can be referred to a mathematical expert. Such matters, however, as mill building and truss design are the daily concern of men who have only a limited knowledge of mathematics. They cannot and will not use the higher methods of designing, even if these are required in safe design; and the sad fact is that they will not, and do not, use ordinary common sense at all times, with the result that a large number of poor designs are turned out.

The writer, during the past 25 years, has been in a position in which few men in the Profession are placed, and is able to make the statement in the foregoing paragraph with emphasis. Called on repeatedly, as he is, to check the designs of others, both recent and ancient, he is thoroughly convinced that what designers need is not more complicated mathematical processes, not more mathematics, but, in fact, less mathematics and more common sense in instruction in designing.

The design of a pair of columns supporting a roof truss, with knee-braces, can be made an exceedingly complicated problem. It can be made so intricate that the average designer could not touch it. Only an expert, and that expert devoting many hours to the problem, could run out all the possibilities of stress of this simple piece of construction. The building would not stand the cost of engineering of this class. Here is the economic situation. What is the outcome? The complex treatment is thrown to the winds, and the truss and columns are designed by rule-of-thumb, and bad rule at that. The columns are designed for direct load only, with no regard to bending moments or wind loads. Frequently, no knee-braces whatever are used, and a flimsy and wabbly building results.

Mr. Godfrey.

On the other hand, the solution of this mill building problem can be rendered as simple as an ordinary truss design by ignoring trivial theoretical matters, by dividing equally between the columns the horizontal force of the wind, and computing the force in the knee-braces and the truss from these applied loads; and a building designed in this manner is both economical and perfectly safe. The average designer can grasp this method quite readily; but our books and engineering literature delight in investing this problem with the greatest complexity, with the result that the majority of designers do not even attempt to approximate its solution, and bad structures grow out of this condition of affairs.

If a fraction of the space taken up with fancy solutions of the mill building problem was devoted to some common-sense simple methods of getting the stresses approximately, and some homely advice was given on how to detail parts, the Profession would be much better off. For example, the writer wished to find (for the head of an engineering school) the details of a mill building where the chords intersect over the support, as an example of good practice in detailing. A thorough search, and inquiry among bridge firms, failed to secure a single case.

As to the question of the need of these higher theories, the mere fact that they are ignored habitually in the design of mill buildings does not argue one way or the other. It is notorious that mill buildings are poorly designed. Much other structural designing is also poor, not because finer theories are neglected, but because common sense is not exercised. The writer would never dream of applying the theory of secondary stresses to a building or bridge, but he has found errors by the hundred, in both design and detail, that would not be possible if designers were instructed in the simple rudiments of proper design that require a knowledge of nothing but the simplest mathematical processes and ordinary mechanics. It is not important for a designer to find that a detail needs 21.1 rivets or 21.3 rivets, but, when a design is turned out and has 11 rivets where about 21 are required, something should be done that will put that designer on the right track.

The members of a cantilever bracket may intersect in the exact center of a truss, just as theory may dictate, and still the bracket may be dependent on the tension in the heads of three or four rivets. This is higher theories with a vengeance!

If steel was perfectly elastic and perfectly brittle, like glass, higher theories would be appropriate and no doubt necessary. Then secondary stresses would loom large in all design. The great Firth of Forth Bridge would then be one of the most dangerous bridges in the world, because of the great secondary stresses due to deflection; but, because steel is tough and not perfectly elastic, that bridge is one of the safest in existence. The tubular members and the rigidly riveted details

Mr. Godfrey.

are the very things that make it so safe, and they are the very things that, theoretically, add tremendously to the stresses. Will engineers ever get this idea?

It is a strange coincidence that the Royal Commission that investigated the Quebec Bridge failure attributed its weakness to the fact that the connections of the compression members were not riveted up. The condition for creating secondary stresses was absent. The same Royal Commission ignored the big traveler, which, being without bracing, upset and pulled the bridge over with it. It does not take even a knowledge of algebra to understand this glaring error.

The Orpheum Theater, in New York City, collapsed, and, in all the reports of its failure, the real cause was ignored. This was a monstrous curved girder, with a span of 74 ft. and a versed sine of 12 ft., connected at the ends to the corners of slender columns.* Among the theories advanced to account for the failure was one, from across the ocean, that attributed it to the twisting in a supporting girder due to deflection of the cross-girders. This is the very limit. It is the theory of secondary stresses carried to its logical limit of absurdity. It is hard to think of anything more misleading and harmful than this kind of theoretical camouflage, not because theoretical speculation in itself is harmful, but because it obscures the facts and takes up space that might be devoted to constructive knowledge of a simple character.

The foregoing instances are given, not because the writer would deprecate the value of theory in engineering design, but would elevate it to a position of usefulness, pure and simple. He would remove it from the condition where it is virtually merely an academic plaything, applied where it has no meaning whatever, and on premises of properties of materials that do not exist in fact. He would make theory agree with facts as they are, and not with conceptions of what might exist if steel and concrete had other properties than they are known to possess; and, lastly, he would simplify theory, so that it is understandable on the part of the men who use it.

Mr. Church.

IRVING P. CHURCH,† ASSOC. AM. SOC. C. E. (by letter).—The writer has been much interested in examining this paper with a view to ascertaining to what extent it supplements the principles and methods proved and exemplified by Castigliano in his classic book‡ on elastic framed systems, or mechanics of the "work of elastic deformation", or of "internal work", as it might also be called.

A very brief résumé of the main theorems proved by Castigliano, therefore, will be undertaken; the elastic framed structure in question being a jointed assemblage of bars and beams (straight or curved), fitted

* *Engineering and Contracting*, February 18th, 1914.

† Ithaca, N. Y.

‡ This book, by A. Castigliano, is entitled "Théorie de l'Equilibre des Systèmes Elastiques", and was published at Turin in 1879.

Mr. Church.

together originally without strain, with the axes of all members lying in a common vertical plane (plane of loading), and with all cross-sections of members symmetrical about that plane.

The notation will be that of the author, with a few supplementary symbols.

Let U denote the total work of elastic deformation (*i. e.*, "internal work") of the frame when loaded. Then, omitting the work of shear, as of very slight consequence, we have

$$U = \sum \int \frac{T_s^2 \, d\,l}{2\,E\,A} + \sum \int \frac{M_s^2 \, d\,l}{2\,E\,I} \quad \ldots\ldots\ldots\ldots (24)$$

Also, the deflection (displacement) of any point of any member, or of a joint, at which point or joint a load or force, P, is applied, this deflection being that taking place in the direction of the line of action of such force or load, will be given by the relation

$$\Delta = \frac{d\,U}{d\,P} = \sum \int \frac{T_s}{E\,A} \left(\frac{d\,T_s}{d\,P}\right) d\,l + \sum \int \frac{M_s}{E\,I} \left(\frac{d\,M_s}{d\,P}\right) d\,l \ldots (25)^*$$

The first term in the right-hand member of Equation (25) is of a general form, so as to provide, not alone for straight bars in which there is direct stress only, but also for bars or beams in which, or in portions of which, T_s or A may not be constant along the length.

For a frame of ordinary straight bars under direct stress of tension or compression, as in a pin-connected bridge truss, Equation (25) reduces to

$$\Delta = \sum \frac{T_s\,l}{E\,A} \left(\frac{d\,T_s}{d\,P}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (26)$$

Similarly, the change of slope, or angular rotation, due to the loading, of the straight line joining any two points of the frame (not joints necessarily) where there are applied two equal parallel forces forming a couple, of moment M, the two forces being at right angles to that line, which is, therefore, the "arm" of the couple, is determined by the relation

$$\alpha = \frac{d\,U}{d\,M} = \sum \int \frac{T_s}{E\,A} \left(\frac{d\,T_s}{d\,M}\right) d\,l + \sum \int \frac{M_s}{E\,I} \left(\frac{d\,M_s}{d\,M}\right) d\,l \ldots (27)$$

(See foot-note following Equation (25)).

Castigliano goes on to treat the case of a frame containing one more bar than is necessary for the frame to hold its shape; this "superfluous", or "redundant", bar being pin-connected at its extremities and of such length that it is too short, or too long, by a small amount,

* A very important restriction on the use of Equation (25), and the other fundamental relations to follow, is that the supporting forces (or reactions) acting on the frame must be "neutral"; that is, the point of application of each such force must not move during the gradual application of the loading, unless along a line at right angles to the line of action of such force.

Mr. Church.

λ_0, to fit into its place after the "necessary" members have been assembled without loading; so that, to fit it into place, special constraint must be exerted. After this "redundant" bar is in place and the frame is loaded, the special constraint having been removed, the direct stress, T' produced in the bar (which carries no load along its length) is found by the relation

$$\frac{d\,U}{d\,T'} = \lambda_0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

Hence, it follows, as a particular case, that, when the "redundant bar" has just the proper length to fit into place originally without strain, the direct stress, T, induced in it when the loading is in position, is determined by the equation

$$\frac{d\,U}{d\,T} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

This has been called the principle of "least work"; as it may easily be proved, by the consideration of a curve (parabola with axis vertical), plotted with U for ordinate and T (as variable) for abscissa, that the special value of T found from Equation (29) is the abscissa of the lowest point of the curve, where the tangent line is horizontal, and, consequently, the corresponding value of U is less than for any other (tentative) value of T.

For finding the deflection, in a given direction, of a point in the frame where there is no load, or at least no load acting in the desired direction, Castigliano uses the device of inserting an imaginary load, P_0, at the point in question and in the desired direction; and later reduces it to zero (as, of course, must finally be done, for correct results). This auxiliary load or force, P_0, which may be called a "dummy" load, and is treated as a variable, will enter more or less into the expressions for T_s and M_s, the differentiation of which expressions with respect to P_0 will give the derivatives, $\left(\frac{d\,T_s}{d\,P_0}\right)$ and $\left(\frac{d\,M_s}{d\,P_0}\right)$. Now, these derivatives will not contain P_0, because, for ordinary frames, only the first power of P_0 can occur in any term of the expressions for T_s and M_s, and hence are not affected when the value of P_0 is made zero. Equation (25) is then used for finding the deflection, with $P_0 = 0$; that is, by substituting in it the foregoing values of the derivatives together with the values of T_s and M_s, as determined from the actual loading alone, P_0 being omitted. Hence, in this case of the "dummy" load, P_0, we have

$$\Delta = \frac{d\,U}{d\,P_0} = \sum \int \frac{T_s}{E\,A}\left(\frac{d\,T_s}{d\,P_0}\right) d\,l + \sum \int \frac{M_s}{E\,I}\left(\frac{d\,M_s}{d\,P_0}\right) d\,l \ldots (30)$$

Mr. Church.

Now $\frac{d\,T_s}{d\,P_0}\left(\text{or } \frac{d\,M_s}{d\,P_0}\right)$ is the rate at which T_s (or M_s) varies with respect to P_0, at a rate of so many pounds (or foot-pounds) per pound of P_0; and furthermore, as T_s (or M_s) is a straight-line function of P_0 (for ordinary "engineering" frames), the value of the rate, $\frac{d\,T_s}{d\,P_0}$, $\left(\text{or } \frac{d\,M_s}{d\,P_0}\right)$, which represents "the slope" of the straight line, is numerically the same as the hypothetical value that T_s (or M_s) would have if P_0 were the only load and had a value of unity.* These hypothetical values may be called T_1 and M_1, respectively. Hence, a ready way of expressing the values of the two derivatives, $\frac{d\,T_s}{d\,P_0}$ and $\frac{d\,M_s}{d\,P_0}$, is to write out what T_s and M_s would be if a unit load were applied at the point in question and in the desired direction, with no other load on the frame. With this change of notation, therefore, Equation (30) becomes

$$\Delta = \sum \int \frac{T_s\,T_1}{E\,A} \cdot d\,l + \sum \int \frac{M_s\,M_1}{E\,I} \cdot d\,l \ldots\ldots\ldots (31)$$

(Castigliano does not use the device of a unit load for finding deflections. It was discovered and adopted independently by the author of this paper in America and by Fraenkel in Europe.)

Castigliano not only uses the device of a "dummy" load for finding deflections, but also that of an imaginary, or "dummy", couple, of moment M_0 (say), applied to the free extremity of a beam in order to find the change of slope, due to the loading, of the tangent to the elastic curve of the beam at that extremity, there being no actual couple at that point. M_0 is finally reduced to zero. As in the previous case of the "dummy" load, T_s and M_s are expressed in terms of M_0 and the other loading, so that the derivatives, $\frac{d\,T_s}{d\,M_0}$ and $\frac{d\,M_s}{d\,M_0}$, may be determined. According to Equation (27) the formula for the change of slope (or rotation) at that point, with the couple in place, is

$$\alpha = \frac{d\,U}{d\,M_0} = \sum \int \frac{T_s}{E\,A}\left(\frac{d\,T_s}{d\,M_0}\right) d\,l + \sum \int \frac{M_s}{E\,I}\left(\frac{d\,M_s}{d\,M_0}\right) d\,l \ldots (32)$$

and when, in this relation, M_0 is made equal to zero, the derivatives retain their values unchanged, while T_s and M_s assume the values proper to them under the actual loading alone, the couple having been removed. As before, as T_s and M_s are almost invariably straight-line functions of M_0, the numerical values of these derivatives are equal, respectively, to the values that T_s and M_s would have if the "dummy" couple had a moment equal to unity and constituted the sole loading on

* Or, to put it another way, the finite change or increment of T_s (or M_s) due to the introduction of P_0 among the loads is proportional to P_0.

Mr. Church.

the frame or beam. Hence, these derivatives become the T_r and M_r, respectively, of the paper, and the result will now read

$$\alpha = \sum \int \frac{T_s T_r}{E A} . d l + \sum \int \frac{M_s M_r}{E I} . d l \ldots\ldots (33)$$

which is the author's Equation (6). This equation is given and proved by Müller-Breslau* in connection with straight and curved beams. He makes very little use of it, however.

In his treatment of single beams, Castigliano rarely finds occasion to use a "dummy" couple, to determine the rotation of a tangent line of the elastic curve; because, when any cross-section forms the extremity of a portion of the beam, considered as a complete beam or frame in itself, apart from the remainder (as, for instance, in dealing with the continuous girder), the flexural couple of the cross-section becomes a part of the external loading for that portion, and is used by Castigliano in expressing the change of slope at that section; in other words, no "dummy" couple is needed in such a case.

By way of a comparative showing of these three methods for finding the change of slope, or rotation, of a tangent line at a definite point of a loaded beam, take the simple case of a straight elastic prismatic beam, fixed horizontally at the left-hand end and loaded at the other (free) extremity with a vertical load, P, and determine the rotation, α, of the tangent at the midway point of the length, from its original horizontal position.

First Method.—Dummy Couple.—Fig. 23.—Conceive a rigid straight bar, with its axis following the tangent in question, to be fastened to the beam at the point, B, by two bolts very near together, and a couple, of moment M_0, to be applied to it, this couple being right-handed, so as to tend to produce a value of α of the same character as that due to the load, P. This bar forms an additional member of the elastic system, and two consequences follow from its being rigid: (1) its axis will remain straight during the gradual loading, always coinciding with the tangent at B, so that the rotation of this "arm" of the couple is the same as that of the tangent; (2) the "internal work" of the bar is zero, so that no terms are needed in Equation (32) to cover the deformation of the bar (that is, its E is infinite).

In Equation (32), therefore, we have: For the elements of length, dx, along the portion, BC:

$$T_s = 0; \text{ whence } \frac{d T_s}{d M_0} = 0;$$

$$M_s = -Px; \text{ whence } \frac{d M_s}{d M_0} = 0;$$

* It is Equation (54a) on p. 133 (see also pp. 69 and 205) of his work entitled: "Die neueren Methoden der Festigkeitslehre und der Statik der Baukonstruktionen." Leipsic, 1893, this equation containing also terms for dealing with a possible change of temperature and slight movement of supports.

and along the portion, $A\ B$:

$$T_s = 0;\ \text{whence}\ \frac{d\ T_s}{d\ M_0} = 0;$$

$$M_s = -P\ (a + x) - M_0;\ \text{whence}\ \frac{d\ M_s}{d\ M_0} = -1.$$

Hence, making $M_0 = 0$ and substituting in Equation (32),

$$\alpha = 0 + 0 + 0 + \frac{1}{E\ I}\int_0^a [-P\ (a + x)]\ (-1)\ d\ x \ldots\ldots (33)$$

that is,

$$\alpha = \frac{P}{E\ I}\left(a^2 + \frac{a^2}{2}\right) = \frac{3}{2} \cdot \frac{P\ a^2}{E\ I} \ldots\ldots\ldots\ldots (34)$$

$$\text{or, as } a = \frac{1}{2}\ l,$$

$$\alpha = \frac{3}{8} \cdot \frac{P\ l^2}{E\ I};$$

as may easily be found by more elementary methods.

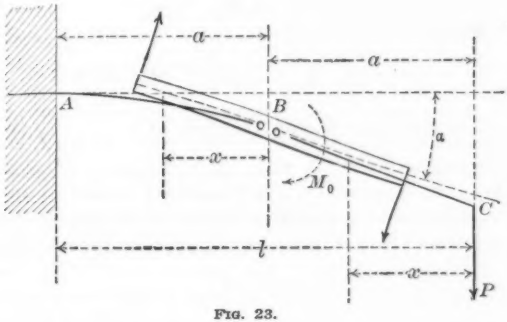

FIG. 23.

Second Method.—Utilizing an Internal Couple.—Fig. 24.—The internal couple, or flexural couple, at section B has a moment we may call M_B, and if the portion, AB, of the beam is considered as a complete elastic system in itself ("free body"), the couple becomes an external couple, as this couple and the vertical shear, J_B, of the section constitute a loading representing the action of the part, BC, conceived as removed, upon the extremity, B, of the portion remaining, AB, now considered in Fig. 24. The flexural couple and shear at A play the part of supporting forces, but their points of application do not move, and this fact justifies the use of Castigliano's theorems.

(Equation (27) could not be applied to the portion, BC, considered by itself, for finding α, because, of the four forces acting on that

Mr. Church. portion, no three, viewed as supporting forces, have motionless points of application. See foot-note following Equation (25)).

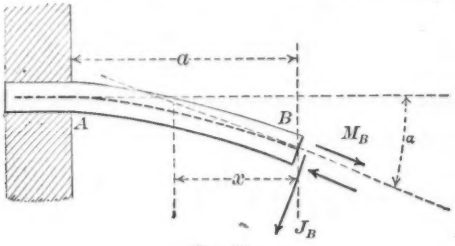

FIG. 24.

For the dx's along AB, we have

$$T_s = 0; \text{ whence } \frac{d\,T_s}{d\,M_B} = 0;$$

$$M_s = -J_B\,x - M_B; \text{ whence } \frac{d\,M_s}{d\,M_B} = -1$$

and hence Equation (27) gives

$$\alpha = 0 + \frac{1}{E\,I}\int_0^a [-J_B\,x - M_B]\,(-1)\,d\,x \ldots\ldots\ldots (35)$$

but $M_B = Pa$, and $J_B = P$, and, therefore, $\alpha = \frac{3}{2} \cdot \frac{P\,a^2}{E\,I}$, as before.

Third Method.—Using an Imaginary Couple of Moment Equal to Unity.—Fig. 25.—Conceive a rigid cross-bar bolted to the beam at section B, and consider a couple applied to it of moment equal to -1 (minus, in order to have it in the same "sense" as the rotation, α, at B),

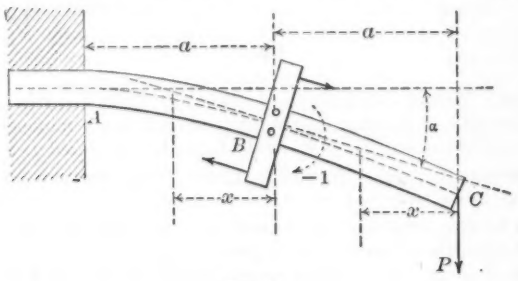

FIG. 25.

this being for the sole purpose of determining T_r and M_r for the successive infinitesimal lengths, dx, along the whole beam, for use in Equation (33).

Mr. Church.

For any dx along BC

$$T_s = 0; \qquad T_r = 0;$$
$$M_s = -Px; \qquad M_r = 0;$$

and for any dx along AB

$$T_s = 0; \qquad T_r = 0;$$
$$M_s = -P\ (a+x); \quad M_r = -1;$$

and hence substitution in the author's Equation (6) or Equation (33) of this discussion, gives

$$\alpha = 0 + 0 + 0 + \frac{1}{E\,I}\int_0^a [-P\,(a+x)]\,(-1)\,d\,x \ldots\ldots (36)$$

$$\text{or } \alpha = \frac{3}{2}\cdot\frac{P\,a^2}{E\,I}$$

In conclusion, it would appear that, in finding the rotation of a tangent line, there is in many cases a decided advantage in using the device of a couple with a moment of unity, so far as the shortening of the routine work is concerned; and the author has rendered an important service in the publication of this paper, with its very direct and convincing proof and numerous applications.

Mr. Parcel.

JOHN I. PARCEL,* ESQ. (by letter).—The author has presented a clear and complete exposition of the rotational work equation, and some very interesting applications, notably the beautifully direct and simple derivation of the three-moment theorem in its general form.

The paper adds another to the many illustrations of the fact that widespread knowledge and full appreciation of new principles in the theory of structures frequently lags considerably behind their discovery. This seems to have been true regarding the "general work equations,"† the principle of "moment areas"‡ (its advocates assert that its scope and importance is still but half appreciated by the Profession generally), and the so-called "slope-deflection" method§, which has recently yielded elegant solutions of certain problems in rigid frames.

In so far as Professor Swain's new principle consists in expressing the angular movement at a given point in the axis of a bar by the method of work, in a manner analogous to that for linear movement,

* Associate Professor, Structural Eng., Univ. of Minnesota, Minneapolis, Minn.

† First stated in their general form by O. Mohr (1874), who also seems to have been the first to realize their vast importance in the analysis of structures. The essential features of Mohr's method, however, were anticipated (according to Müller-Breslau) by Maxwell (1864), and the fundamental principle was enunciated by Clapeyron in 1833.

‡ Generally ascribed to Mohr (1868), but developed independently in a somewhat different form by the late Charles E. Greene, M. Am. Soc. C. E. (1874). Its wide use in America is of comparatively recent date.

§ Applied by Mohr to the secondary stress problem as early as 1891 (*Zivilingenieur*, 1892, p. 577), but attracting little attention for many years. Presented as a general method of attack for a variety of problems in rigid frames by G. A. Maney ("Studies in Engineering, No. 1," University of Minnesota, 1915).

Mr. Parcel. it is not new. English and American treatises* on the theory of structures, as a rule, give a very restricted and inadequate presentation of the "method of work." German (and other continental European) treatises, however, lay considerable stress on the generality of the work equations, noting that Δ (to follow the notation of the author's Equations (1) and (2)) is linear or angular displacement, according as the "unit loading" which produces t and Mt is a unit force or a unit couple. Some of these works develop equations similar to the author's Equation (6), and give elementary examples of the calculation of angular change;† but the principle seems to be little understood (or at least little appreciated) generally, and Professor Swain has rendered no small service to the Profession by his excellent presentation.

Mr. Mensch. L. J. MENSCH,‡ M. AM. SOC. C. E. (by letter).—The principle of virtual displacements is one of the most general laws of equilibrium, and in it are contained the theory of least work, Maxwell's and Betti's reciprocal theorems, and Professor Swain's principle. These various rules are either identical or differ only in algebraic expressions of force, moment, and displacement.

The principle of virtual displacements says: The work performed by the exterior forces and reactions when acting on a structure in a state of equilibrium equals the work done by the interior forces in deforming the structure, which principle can be written in the form

$$\Sigma P \cdot \Delta = \Sigma T_s \cdot \Delta\, d\, l + \Sigma M_s \cdot \Delta\, d\, \alpha \ldots\ldots\ldots\ldots (1)$$

where P denotes the exterior forces and reactions;

Δ denotes their corresponding displacements at the point of application in the direction of the forces;

Δdl denotes the change of length of the length, dl, due to the normal forces, T_s, produced in the structure by the forces, P;

and $\Delta d\alpha$ denotes the change of angle of an element, dl, due to the moments, M_s, produced in the structure by the forces, P.

All expressions are in the familiar shape: Work equals force multiplied by displacement in the direction of the force; and the correctness of Equation (1) appears to be very plausible.

* See, however, D. A. Molitor, M. Am. Soc. C. E., "Kinetic Theory of Engineering Structures", pp. 18 and 28–29. The exposition is much less complete than in the references cited below.

† See, especially, F. Hartmann, "Die Statisch Unbestimmten Systeme des Eisen und Eisen-betonbaues" (1913), pp. 9–11 and 24–33; also G. C. Mehrtens, "Statik und Festigkeitslehre" (1910), pp. 203–204 and 215 *et seq.*; H. F. B. Mueller-Breslau, "Die Graphische Statik der Baukonstruktionen", Band II, Erste Abtheilung (1903), pp. 14–17; and "Die Neueren Methoden der Festigkeitslehre" (1904), pp. 59 and 84–85. Mueller-Breslau seems to claim for himself the honor of the discovery of Professor Swain's new principle (see his "Graphische Statik", above cited, pp. 52–57). He states that in the 1886 edition of his "Festigkeitslehre", he first showed that the work equations (which he calls Maxwell's equations) apply to "rotation" as well as "translation."

‡ Chicago, Ill.

Mr. Mensch.

Clapeyron has shown that the actual work performed by gradually applied forces must be half of that above given, and the validity of Equation (1) is not changed by dividing each side by 2. Clapeyron has also shown that the validity of Equation (1) is not changed, when we substitute

First: for the forces and reactions, P, another set of forces, P', and their corresponding reactions, as long as the second set of forces and reactions hold the structure in a state of equilibrium; and

Second: The new forces, T', and the new moments, M', produced by the new set of forces and reactions, P', the displacements and deformations of the first set of forces being retained in Equation (1).

The new equation may be written

$$\Sigma P' \cdot \Delta = \Sigma T' \cdot \Delta d l + \Sigma M' \cdot \Delta d \alpha \ldots\ldots\ldots\ldots (2)$$

The new forces, P', and the new stresses, T' and M', have evidently nothing to do with, and are entirely independent of, Δ, Δdl, and $\Delta d\alpha$, of the first set of forces; their only co-relation is that each set belongs to a state of equilibrium; Δ, Δdl, and $\Delta d\alpha$, therefore, are called possible or virtual displacements. This is easily proved in the case of the simple structure shown in Fig. 26, consisting of three bars, supported at A and B and affected by a load, P, at C. The three bars undergo certain elongations and shortenings, producing a definite displacement at C. It is clear that any other load will produce stresses and displacements which are in direct proportion to the values of the two loads; and a load of $\frac{P}{2}$, for example, will produce half the stresses and half the changes of length, and also only half the displacement at C. For this case Equation (1) may be written, also, in the form

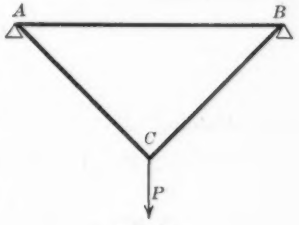

FIG. 26.

$$\Sigma \frac{P}{4} \Delta = \Sigma \frac{T_s}{4} \cdot \Delta d l.$$

$\frac{P}{4}$ and $\frac{T}{4}$ may be considered as new forces and stresses which are in a state of equilibrium, and Δ and Δdl are the old displacements. It was soon found that P, in Equation (1), and P', in Equation (2), are not necessarily forces, but may be moments, the latter being nothing else

Mr. Mensch.

than a couple of equal forces acting at a distance, o, for example. We can say

$$M = P \cdot o;\ \Delta = o \cdot \alpha;\ M = P \cdot \frac{\Delta}{\alpha};\ M \cdot \alpha = P \cdot \Delta \ldots\ldots (3)$$

and Equations (1) and (2) become

$$\Sigma M \cdot \alpha = \Sigma T_s \cdot \Delta\, d\, l + \Sigma M_s \cdot \Delta\, d\, \alpha \ldots\ldots\ldots\ldots (4)$$

$$\Sigma M' \cdot \alpha = \Sigma T' \cdot \Delta\, d\, l + \Sigma M' \cdot \Delta\, d\, \alpha \ldots\ldots\ldots\ldots (5)$$

which equations express Professor Swain's idea in another form. Maxwell has deduced from Equation (2) a reciprocal theorem, relating to the effect produced in a structure by two different forces:

"A force, 1, in a point, A, of a structure in a state of equilibrium, will produce in any other point, B, of the same structure, a displacement, d_{ba}, which is equal to the displacement, d_{ab}, in the point, A, in the direction of the first force, 1, produced by another force, 1, acting in B in the direction, d_{ba}."

A more general theorem is due to Betti. Müller-Breslau claims that he has first shown that Maxwell's principle can also be applied to moments and to changes of angles, namely: "A moment, 1, acting in any point, A, produces a rotation in any point, B, which is equal to the rotation produced in A by a moment, 1, acting in B", which is, again, Professor Swain's principle expressed in another way.

Equations (2) and (5) can be transformed into a more useful shape by substituting

$$\Delta\, d\, l = \frac{T_s}{E\, A} \cdot d\, l \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

$$\Delta\, d\, \alpha = \frac{M}{E\, I} \cdot d\, l \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

thus obtaining

$$\Sigma P' \cdot \Delta = \Sigma \frac{T_s \cdot T' \cdot d\, l}{E\, A} + \Sigma \frac{M_s \cdot M' \cdot d\, l}{E\, I} \ldots\ldots\ldots (8)$$

$$\Sigma M' \cdot \alpha = \Sigma \frac{T_s \cdot T' \cdot d\, l}{E\, A} + \Sigma \frac{M_s \cdot M' \cdot d\, l}{E\, I} \ldots\ldots\ldots (9)$$

Replacing the moments, M', in Equation (9) by only one moment of the value, 1, and by its proper reactions, and under the assumption that the supports are immovable in the direction of these reactions, so that the work of the reactions is nil, then, and then only, Equation (9) becomes

$$\alpha = \Sigma \frac{T_s \cdot T' \cdot d\, l}{E\, A} + \Sigma \frac{M_s \cdot M' \cdot d\, l}{E\, I} \ldots\ldots\ldots (10)$$

where T' and M' are the normal forces and moments produced in the structure by the moment, 1, and its reactions, which equation is identical with the author's Equation (6).

Mr. Mensch.

Similarly, Equation (8) is transformed by the assumption of only one force, 1, acting on a structure with immovable supports in the direction of the reactions

$$\Delta = \Sigma \frac{T_s \cdot T' \cdot d\,l}{E\,A} + \Sigma \frac{M_s \cdot M' \cdot d\,l}{E\,I} \quad \ldots\ldots\ldots (11)$$

T' and M' being the normal forces and moments produced by the force, 1, and its reactions.

Castigliano has deduced, from the principle of virtual displacements, another rule for finding the displacement of any point of a structure. He replaced the set of forces in Equation (1) by another set of forces which varied from the first only in this respect, that all forces of the old set remained the same except that the force, P_n, acting in the point, n, the displacement of which is to be found, is changed by the infinitesimal quantity, δP_n. The interior forces will then be changed, also, by the infinitesimal values, δT_s and δM_s.

Provided the work of the reactions due to δP_n is nil, Equation (1) becomes

$$\Sigma P \cdot \Delta + \delta P_n \cdot \Delta_n = \Sigma (T_s + \delta T_s) \cdot \Delta\, d\,l + \Sigma (M_s + \delta M_s) \cdot \Delta\, d\,\alpha . \quad (12)$$

Subtracting Equation (1) from Equation (12) and dividing by δP_n

$$\Delta_n = \Sigma \frac{\delta T_s}{\delta P_n} \cdot \Delta\, d\,l + \Sigma \frac{\delta M_s}{\delta P_n} \cdot \Delta\, d\,\alpha$$

Introducing again Equations (6) and (7)

$$\Delta_n = \Sigma \frac{\delta T_s}{\delta P_n} \cdot \frac{T_s \cdot d\,l}{E\,A} + \Sigma \frac{\delta M_s}{\delta P_n} \cdot \frac{M_s \cdot d\,l}{E\,I} \quad \ldots\ldots\ldots (13)$$

and, similarly, for moments,

$$\alpha = \Sigma \frac{\delta T_s}{\delta M_n} \frac{T_s \cdot d\,\alpha}{E\,A} + \Sigma \frac{\delta M_s}{\delta M_n} \frac{M_s \cdot d\,l}{E\,I} \quad \ldots\ldots\ldots (14)$$

These equations are practically identical with Equations (10) and (11), as will be shown later.

Evidently,

$$T_s \cdot \frac{\delta T_s}{\delta P_n} = \frac{\delta T_s^2}{2\,\delta P_n},$$

$$M_s \cdot \frac{\delta M_s}{\delta P_n} = \frac{\delta M_s^2}{2\,\delta P_n}$$

hence, Equations (13) and (14) become

$$\Delta_n = \frac{\delta \left(\Sigma \frac{T^2\, d\,l}{2\,E\,A} + \Sigma \frac{M^2\, d\,l}{2\,E\,I} \right)}{\delta P_n} \quad \ldots\ldots\ldots (15)$$

$$\alpha = \frac{\delta \left(\Sigma \frac{T^2 \cdot d\,l}{2\,E\,A} + \Sigma \frac{M^2 \cdot d\,l}{2\,E\,I} \right)}{\delta M_n} \quad \ldots\ldots\ldots (16)$$

Mr. Mensch.

The expressions in the denominator are those of Clapeyron for the actual work performed by gradually applied forces acting on a structure in equilibrium, and Equations (13) to (16) simply state that the displacement or the rotation of a point, n, acted on by a force, P_n, or a moment, M_n, equals the first partial derivative of the expression for the work of the gradually produced interior forces, taken according to δP_n or δM_n.

At an immovable support, Δ or α must be nil, hence the first derivative must be zero. This can only happen for a condition where the work is a maximum or a minimum. It can be easily shown that the work cannot be a maximum, hence it must occur at a minimum. Therefore, Equations (13) to (16) have been called the principle of least work. If it is desired to find the displacement of any point at which no force happens to act, it is assumed that a fictive force or moment is acting at that point, P_n or M_n; the general expressions for the work performed by all the forces and moments and P_n and M_n are written down, the first derivative is found, and in this derivative and the general equation of the moment, P_n and M_n are assumed to vanish. The normal forces and moments produced in any structure by a single load or moment, being always linear functions of P_n or M_n, it follows that $\frac{\delta T}{\delta P_n}$ and $\frac{\delta M}{\delta M_n}$ are, in fact, the values of the normal forces and moments corresponding to $P_n = 1$ and $M_n = 1$.

In applying any of these methods to actual structures, great care must be taken first to transform an indeterminate structure into a so-called statically determinate system by the assumption of the proper reactions or forces; one must always consider that the reactions count just as heavily as any other force, and that any movement of the abutments will contribute to the work performed by the exterior forces and must appear on the left side of Equations (1) to (16). If, for example, one abutment has a displacement, e, in the direction opposite to the reaction, R, and a rotation, t, in the direction of the moment of the reaction, O, then there must be added to the left of:

Equation (1) $\quad - R \cdot e + O \cdot t$

(10) $\quad - R' \cdot e + O \cdot t$, when R', V', and O are the reactions due to $P'' = 1$ and $M' = 1$,

(13) and (15) $\quad - \frac{\delta R}{\delta P_n} \cdot e + \frac{\delta O}{\delta P_n} \cdot t$

(14) " (16) $\quad - \frac{\delta R}{\delta M_n} \cdot e + \frac{\delta O}{\delta M_n} \cdot t$

To show that the theory of least work is practically identical with the author's principle, his Case II will be solved by that principle, and

it will be assumed that a moment, M_n, instead of a moment, 1, is acting at the right end of the beam; then, evidently, Mr. Mensch.

$$\text{for the left of } P \ldots M_s = P \,.\, x \,.\, \frac{(l-a)}{l} + M_n \,.\, \frac{x}{l} \left\| \frac{\delta\, M_s}{\delta\, M_n} = \frac{x}{l} \right\| M_n = 0 \text{ in } M_s$$

$$\text{“ “ right of } P \ldots M_s = P \,.\, a \,.\, \frac{l-x}{l} + M_n \,.\, \frac{x}{l} \left\| \frac{\delta\, M_s}{\delta\, M_n} = \frac{x}{l} \right\| M_n = 0 \text{ “ } M_s$$

and this, introduced in Equation (14), gives

$$\alpha = \int_0^a \frac{x}{l} \,.\, \frac{P\,x\,(l-a)}{l}\, d\,x + \int_a^l \frac{x}{l}\; P \,.\, a \,.\, \frac{l-x}{l}\, d\,x \ldots\ldots$$

which is identical with Professor Swain's Equation (9).

Nothing is saved in the integrations, but Professor Swain saves the writing down of two expressions affected by δM_n.

If it is desired to find the displacement and rotation of a point of a fixed arch, and if the same method is used as that shown in the author's Case II, it would lead to rather long formulas.

By a happier choice, of transforming the indeterminate structure into a statically determinate system, very much simpler expressions can be obtained. Fig. 27 shows how the arch may be transformed into a cantilever by assuming that, at the point, B, where the displacement is to be found, the right end of the arch is cut off, and at that section a horizontal force, a vertical force, and a moment, are applied to re-establish the equilibrium. In order to find the displacements by Professor Swain's principle, there is applied, besides, a horizontal and a vertical force, 1, at that section, and a moment, 1, and these new forces must be counterbalanced by the proper reactions at the left abutment.

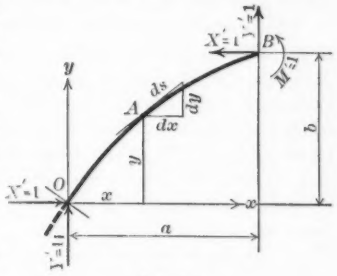

FIG. 27.

M_s, at any point, x, y, is again the moment of the forces acting on the structure the deflection of which it is desired to find. The indeterminate values of the reactions must duly appear in the expression for the moment.

T_s is the corresponding normal force.

$M' = 1$ will produce, in any point, x, y, a moment 1;

$X' = 1$ “ “ “ “ “ “ “ “ $(b - y)$ and a normal force $\left(1 \,.\, \frac{d\,x}{d\,s}\right)_s$;

$Y' = 1$ will produce, in any point, x, y, a moment $(a - x)$ and a normal force $\left(-1 \,.\, \frac{d\,y}{d\,s}\right)$;

Mr. Mensch.

hence, the change of angle of the arch between the point, O, and the point, B,

$$\alpha = \int_0^a \frac{M_s \cdot 1 \cdot ds}{EI} = \int_0^a \frac{M_s \cdot ds}{EI} \quad \ldots\ldots\ldots\ldots (17)$$

the horizontal displacement of the point, B, in the direction, $X' = 1$,

$$\Delta_x = \int_0^a \frac{T_s \cdot \frac{dx}{ds} \cdot ds}{EA} + \int_0^a \frac{M_s (b - y) \cdot ds}{EI}$$

$$= \int_0^a \frac{T_s \cdot dx}{EA} + b\int_0^a \frac{M_s \cdot ds}{EI} - \int_0^a \frac{M_s \cdot y \cdot ds}{EI} \ldots (18)$$

the vertical displacement of the point, B, in the direction, $Y' = 1$,

$$\Delta y = \int_0^a \frac{T_s \cdot \left(-\frac{dy}{ds}\right) \cdot ds}{EA} + \int_0^a \frac{M_s \cdot (a - x) \cdot ds}{EI}$$

$$= -\int_0^a \frac{T_s \cdot dy}{EA} + a\int_0^a \frac{M_s \cdot ds}{EI} - \int_0^a \frac{M_s \cdot x \cdot ds}{EI} \ldots (19)$$

which equations will be found useful in many arch problems.

The author's treatment of Cases VI and VII cannot be said to be new. The same cases and very many others are identically treated by Müller-Breslau,* and it is the writer's impression that the French engineers of the Paris Fair of 1878 designed the many arched structures of the exhibition buildings by this method; also that a description of the method appeared† at about that time. Müller-Breslau has also shown how to simplify greatly the calculations, especially in structures of a symmetrical shape. For example, he transforms the arch structure, shown in Fig. 28, into a kind of statically determined continuous structure in which the left abutment is only able to take vertical reactions of the same amount as those which would be taken by a common girder, and he connects the left end of the arch by an absolutely rigid body with the apex at O, at which point, in order to re-establish the equilibrium, he applies the horizontal thrust, X, the moment M_0, and the indeterminate portion of the vertical reaction, Y. He proves that the point, O, must be the center of gravity

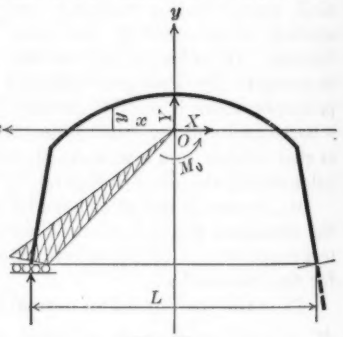

FIG. 28.

* "Graphic Statics of Indeterminate Structures", 1892.

† In *Le Génie Civil.*

of the so-called elastic weights, $\frac{d\,s}{I}$, of each point of the structure, and Mr. Mensch.

if this point is taken as the axis of a system of co-ordinates and M'' are the moments of a statically determined system which rests on rollers, and on which no indeterminate reactions are acting, in fact, when M'' is the common moment of a common beam, then,

$$X = \frac{\int_0^l \frac{M'' \,.\, x \,.\, d\,s}{E\,I}}{\int_0^l \frac{x^2 \,.\, d\,s}{E\,I}} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

$$Y = \frac{\int_0^l \frac{M'' \,.\, y \,.\, d\,s}{E\,I}}{\int_0^l \frac{y^2 \,.\, d\,s}{E\,I}} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21)$$

$$M_0 = \frac{\int_0^l \frac{M'' \,.\, d\,s}{E\,I}}{\int_0^l \frac{d\,s}{E\,I}} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

which are, of course, very much simpler expressions than the often extremely sensitive, and always very involved, Equations (19), (20), and (21), of the author.

French engineers, for nearly 40 years, have been very successful in finding still more important short-cuts in the design of indeterminate structures, and the writer confesses that he would have never designed and built indeterminate structures if these short-cuts, and others which he developed himself, had not reduced the labor of computation often to 10% and sometimes even to 1% of that required according to the methods shown in the ordinary textbooks.

To compute the simplest arch by the ordinary methods in vogue is a considerable task, if the change of the moment of inertia, the change of temperature, and the shortening of the arch are duly taken into consideration. If, in addition, the displacement and rotation of points are to be found, in order to decide about expansion joints in reinforced concrete bridges, it will take the best engineer, if he is not an expert in arch design, probably many weeks of steady and hard work to design a bridge. Generally, the work is done very roughly, temperature and shortening stresses are neglected, and to find displacements of points is not dreamed of. This explains the fact that many bridges crack, although designed with a large factor of safety, also the fact that most American arched bridges, on account of the uncertainty of the designer, are in general very much heavier than those of European design.

Mr. Mensch.

It is very important to know that the application of the principles as here developed have many limitations, *viz.:*

(1) The structure must be in a perfect state of equilibrium.
(2) The deformations must be extremely small.
(3) The stresses must be within the elastic limit, and must follow Hooke's law.
(4) There must be absence of all vibration.
(5) It is assumed that all the work performed by the exterior forces is consumed by the work in deforming the structure, and that the production of heat, and chemical and crystallographic changes are neglected.
(6) Changes of temperature must be computed separately.
(7) Secondary stresses are neglected.
(8) The work in overcoming friction at the abutments or joints is neglected.
(9) Poisson's ratio is neglected.
(10) The influence of the curvature of the structure is neglected.
(11) It is not permitted to apply indiscriminately the statics of a rigid body. In a framed structure, for example, where a force is acting at a lower joint, it is not permitted to assume that its point of application might be indifferently at any point of its line of action. If the line is extended to the upper chord, it would probably produce bending there, and the work done would be quite different.
(12) The influence of shearing forces (of great importance in dams, for example), is neglected.

These limitations apply to both determinate and indeterminate systems, and have as yet received comparatively little study by investigators. Some of these points, however, are of great importance, and the figures may be out 50% and more; and in many structures one cannot predict the factor of safety.

Of the utmost importance is the behavior of materials when it differs from Hooke's law, as when a structure is stressed beyond the elastic limit, or, as in concrete construction, where the time-flow or the plasticity of the concrete might reduce the modulus of elasticity for the dead-load stresses to perhaps one-tenth of the value of that under a short-time load. As a rule, the factor of safety is increased, due to the flow of the material, and the stresses in the dangerous section remain nearly constant with gradually increased loads, and the comparatively stronger parts take up more stresses than have been computed until a new state of equilibrium is reached.

Mr. Turneaure.

F. E. TURNEAURE,* M. AM. SOC. C. E. (by letter).—This paper presents a very interesting development of a principle in the theory of

* Madison, Wis.

Mr. Turneaure.

structures which, so far as the writer knows, has not been made use of heretofore. The principle itself is not exactly new to the writer, and its application to the determination of stresses in redundant members, or the determination of redundant reactions, is quite fully set forth in his revision of Johnson's "Framed Structures", Part II, 1910. Chapter VI of this work reviews, in the first few pages, the general principles and formulas used in the determination of redundant stresses, and then applies these principles to quite a variety of selected problems. In the general formula, Equation (5), page 335, of this work, an equation is given expressing the relation between redundant stresses, S_1, S_2, S_3, etc., and the stresses and bending moments due to the external loads. Following this equation, the statement is made:

"Instead of assuming as the unknowns the various direct stresses, S_1, S_2, etc., it is sometimes more convenient to take certain of the bending moments as the unknowns, or certain direct stresses together with certain moments. In this case the values of u, and m_1, corresponding to an unknown bending moment, M_1, are respectively the stresses and moments in the various members due to a bending moment of unity in the redundant member. The resulting equations are then the same as Equation (5) excepting that certain unknown moments, M_1, M_2, etc., are used instead of the stresses, S_1, S_2, etc."

The general method thus fully set forth, applied to the problem given by Professor Swain as Case VI, would, on substitution of the proper notation in Equation (5) referred to, produce precisely his Equations (16), (17), and (18). In presenting this method of attack, it was also recognized by the writer, as indicated in the subsequent article, especially on page 336, that the quantities, $\Sigma \frac{s\,l}{E\,A} \cdot u_1$ and $\Sigma \int \frac{M\,d\,x}{E\,I} \cdot m_1$ (identical with those of Professor Swain's Equation (4)), represent the change in angle of the member under the actual conditions of loading, the quantities, u_1 and m_1, being the direct stress and bending moment, respectively, in any member due to a unit moment applied at the point the angular change of which is desired.

While thus setting forth the practicability of applying unit bending moments as well as unit forces in problems of this kind, the writer, as a matter of fact, did not follow this method in numerical problems, primarily for the reason that the solution adopted in any particular case was that which appeared to be the most convenient and expeditious. For example, in the solution of various problems of portals or quadrangular frames fixed at the base, the method for arches was generally used. This method assumed as the redundant quantities the shear, thrust, and bending moment at the crown. Three equations for the determination of these three unknown quantities were derived by equating the horizontal and vertical components of deflection and the angular change at this point for the two sides of the arch. The expres-

Mr. Turneaure.

sion for the angular change of the arch axis at the crown is really identical with the form of expression derived by Professor Swain, although it is apparent that a mere familiarity with this expression would not be apt to lead to the generalization in Professor Swain's paper. His explanation of how this principle may be applied in determining changes of inclinations of any member of a structure is very interesting, and will doubtless prove of value in many practical problems.

Referring to the foot-note on page 622, in which Professor Swain explains the character of the units in Equation (1), it seems to the writer to be somewhat more logical to consider that the quantity, t, is merely a ratio, or an abstract number, which, multiplied by $\frac{s\,l}{E\,A}$, results in a length. The quantity, $\frac{s\,l}{E\,A}$, is the actual change in length or movement of the member distorted, and the quantity, t, is simply a factor by which this change in length is multiplied in order to determine the contribution of this particular member to the deflection desired. It is a mere ratio, and when determined by the ordinary process of calculating the stress in a member due to a unit load, it represents, not the stress itself, but the ratio of stress to load; but, the load happening to be unity, the numerical value of the ratio is the same as that of the stress. This factor or ratio, t, can be determined in other ways, as, for example, by the principle of virtual velocities, or by the principle of work, or by applying differential calculus to the linear dimensions of the framework. In any case, it may be looked on as simply a ratio, and hence the product of this ratio multiplied by the length is a length.

Mr. Maney.

G. A. MANEY,* ESQ. (by letter).—The writer submits the following discussion on the "slope-deflection" method† as applied to frame analysis:

A difficulty in the analysis of frames for concrete ships is found in the irregularity in their make-up and the inapplicability of ordinary methods to secure accurate results.

The transverse framing of a concrete ship consists generally of a large number of members, of varying stiffness, connected by rigid joints, and continuous throughout. Many of these members have great variation in stiffness throughout their length, others are curved, and

* Senior Structural Engineer, Engineering Section, Emergency Fleet Corporation, Philadelphia, Pa.

† The so-called slope-deflection method, as first treated by the writer, was published in "Studies in Engineering, No. 1" of the University of Minnesota, in 1915. A special application of this method was made shortly afterward in *Bulletin No. 80*, of the University of Illinois Engineering Experiment Station, in a paper on "Wind Stresses in Office Buildings." On p. 412 of the "Concrete Engineers' Handbook", by Messrs. Hool and Johnson, credit is given to the writer for the method for the general treatment of rigid frames, which is used in Chapter 10, on "Moments in Rigid Building Frames."

still others are arches in their mode of action, and vary as to loading and end conditions. Mr. Maney.

Perhaps the most unusual problem is that of a rigid frame having one or more of its members as irregular arches, with ends neither fixed nor free, but subjected to a degree of restraint determined entirely by the relative stiffness and loading of all the members of the structure.

In treating this problem, the method developed by the writer is similar to that described by Professor Swain in that the tangent direction or slope of the elastic curve of the member, at certain critical points, is used as a medium.

Discussion and Derivation of Method.—The end conditions of any member subjected to any possible distortion (in one plane) due to flexure, may be expressed or defined by certain functions of the elastic curve which will be called S_A, S_B, R_v, and R_H. Each of these quantities, as used in the calculations, is some multiple of the tangent

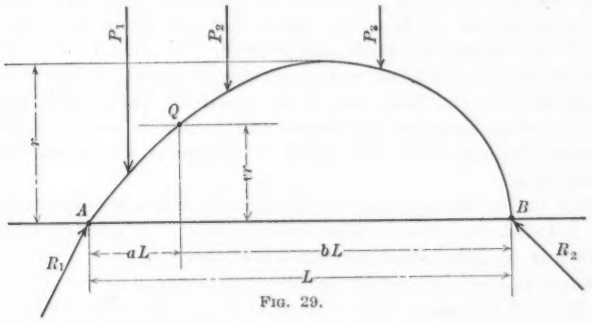

FIG. 29.

values of small angles. The angles, in turn (or their tangents), are measured by the quotients of certain deflections divided by distances on the member in question.

Any condition of distortion, as determined by these end conditions in combination with certain loads applied between the ends of the member, can be effected by the application of certain end moments, M_A and M_B, together with a force, F, at one end, applied in the direction of the line, AB, connecting the ends. The general expression for the bending moment, M, at any section, for the most general case of a curved member with flexure in the plane of the member only, takes the following form:

$$M = a\,M_B + b\,M_A + r\,F\,r + M' \ldots\ldots\ldots\ldots (1)$$

The quantities, a, b, r, v, and M' will be defined with the aid of Fig. 29.

Mr. Maney.

a is a ratio of the distance from A to the projection of any point, Q, on the line, AB, connecting the ends of the member, divided by the length of AB;

b is this ratio where the distance to the projection of any point is measured from B;

r is the rise, or distance, measured at right angles, from AB to the point on the axis of a curved member which is farthest from AB;

v is the ratio of this same distance for any other point to the distance, r;

M' is the bending moment at any point which is calculated on any statically determinate basis.

In general, M' is assumed to be zero at the ends of the member. Then, any direction of one reaction (as R_1) is assumed, and its value is calculated by taking moments of the forces about B and equating to zero. R_2 may then be determined, both as to value and direction. The member now being in equilibrium under applied loads, the value of M' for all the points along the axis (ten are generally sufficient) may be calculated. It becomes evident that any set of M' values consistent with the applied loads may be used.

In order to make these end conditions of the elastic curve of the general member the unknowns to be solved for, rather than the unknown bending moments and thrusts at the ends, it becomes necessary to express the latter (M_A, M_B, and $F\,r$) in terms of the former (S_A, S_B R_v, and R_H).

This can be done because of the definite and well-recognized relations between the extreme fiber deformations of a member subjected to bending, and the accompanying deflections.

Before this is done, a more definite statement concerning S_A, S_B, R_v, and R_H, will be made. These quantities are all ratios which, when multiplied by L (for S_A, S_B, and R_v) or by r (for R_H), will give certain multiples of deflection values. The deflections, $S_A\,L$, $S_B\,L$, and $R_v\,L$, are all measured in a direction at right angles to the line, $A\,B$.

The deflection of the end, A, from a tangent to the elastic curve at B, and in a direction at right angles to $A\,B$, is equal to $R_v\,L$, or $S_B\,L$, or a combination of the two, depending on the final direction of the line between the ends relative to its initial direction. In the general formula, this deflection must be made a function of both R_v and S_B. Also, the deflection of the end, B, from a tangent to the elastic curve at the end, A, will be a function of both R_v and S_A. The deflection of either end with respect to the other, which takes place in a line between these, is measured by the quantity, R_H.

To the foregoing deflections, are equated their values, in terms of the bending moment at any section. As before indicated, this moment value will be a function of the unknown moments, M_A, M_B, and $F\,r$,

which are the values to be found as a result of a solution by this method. Mr. Maney.

The member under consideration will be divided into ten or more sections, having no necessary relation to each other, as far as relative length and stiffness is concerned. The value of $\frac{l}{I}$ for each section is obtained, l being the axial length of the section and I the average moment of inertia. The calculation of the values of $\frac{l}{I}$ is simplified by the consideration that only relative values of these quantities need be used.

By means of the relation between the deformation of the extreme fibers in a bending member and its deflections, the value of these deflections will be expressed in terms of the bending moments which determine extreme fiber unit deformations.

Consider any small length, l, along the axis of any member subjected to bending stress, over which M is the average bending moment and I is the average moment of inertia. Applying the fundamentals of deflection, it will be found that $\sum_B^A b\,L\left(\frac{M\,l}{E\,I}\right)$ equals the deflection of the end, B, from a tangent to the member at A, and in a direction at right angles to $A\,B$. Therefore:

$$b\,L\left(\frac{M\,l}{E\,I}\right) = R_v\,L - S_A\,L.$$

$$\text{Likewise } a\,L\left(\frac{M\,l}{E\,I}\right) = S_B\,L - R_v\,L;$$

$$\text{and } v\,r\left(\frac{M\,l}{E\,I}\right) = R_H\,r.$$

Then, neglecting the value of E, which is common to all the equations, and knowing that only relative values of $\frac{l}{I}$ are necessary, the simpler form of these three fundamental equations of deflection are obtained:

$$b\,M\left(\frac{l}{I}\right) = R_v - S_A \quad \ldots\ldots (2)$$

$$a\,M\left(\frac{l}{I}\right) = S_B - R_v \quad \ldots\ldots (3)$$

$$v\,M\left(\frac{l}{I}\right) = R_H \quad \ldots\ldots (4)$$

In these equations it is necessary to govern the signs of the $\left[b\,M\,\frac{l}{I}\,(\text{etc.})\right]$ quantities by one method, and the signs of S and R by an entirely different scheme.

Mr. Maney.

Also, the general frame problem must be divided into two entirely different phases. In one of these the object is to determine the effect of end conditions and loads on a curved member of varying stiffness, with regard to the distribution of moments throughout the length of the member. The common problem of the hingeless reinforced concrete arch is one of the simple forms of this problem, where the quantities, S and R, which determine the end conditions, are zero. In a problem of this sort, the bending moment at any section of a member will be considered as plus or minus, according as it produces tension on the lower or upper extreme fiber. Lower or upper extreme fibers may be determined entirely by a separate sketch of the member in any position, without relation to its exact relative position or orientation in the structure.

After finding the effect of all possible end conditions and applied loads on the end moments of this member, M_A and M_B, the sign of each of these moments is determined by its effect on the rotation of the joint in the structure to which it is adjacent. If it tends to rotate the joint clockwise it will be given a plus sign, and if counter-clockwise, a minus sign.

In any straight member, an individual solution to find the effect of applied loads and end conditions is not necessary. The moment at any end, A, of a straight member, AB, with uniform stiffness may be expressed in the general form:

$$M_A = M_{F_A} + \frac{2EI}{L}(3R_v - 2S_A - S_B) \quad \ldots\ldots\ldots (5)$$

M_{F_A} is the fixed beam moment at A which gives the effect of applied loads when the end conditions are zero. This case is that of a fixed beam for a straight member, or a hingeless arch for a curved member.

For any end conditions other than those expressed by zero values of R and S, the effect of end slope values, S_A and S_B, and the relative end deflection, R_v, on the final moment, M_A, may be obtained by a direct algebraic addition of the end moments due to these quantities, to M_F.

It should be noted that the values of these end conditions, S and R, are determined entirely with reference to the original direction of the line connecting the ends of the member in its unstrained conditions.

Also, a clockwise rotation of the end slope values of the elastic line will make S_A and S_B plus, and a counter-clockwise rotation, minus. Similarly, if either end rotates in a clockwise direction relative to the other end, R_v will be plus.

When the general expression for M, as given by Equation (1), is substituted in Equations (2), (3), and (4), the following equations are obtained, and these, when solved simultaneously, will give perfectly general values for M_A and M_B, as well as Fr. This last quantity measures the effect of end thrust in the direction, AB, on all the

moments, and it will readily be seen that in any straight member this will not affect the moments in any primary sense: Mr. Maney.

$$\Sigma\, b \frac{l}{I}(b\, M_A + a\, M_B + v\, F\, r) = -S_A + R_v - \Sigma\, b \frac{l}{I} M'$$

$$\Sigma\, a \frac{l}{I}(b\, M_A + a\, M_B + v\, F\, r) = -R_v + S_B - \Sigma\, a \frac{l}{I} M'$$

$$\Sigma\, v \frac{l}{I}(b\, M_A + a\, M_B + v\, F\, r) = +R_H \qquad - \Sigma\, v \frac{l}{I} M'$$

These three equations are solved on page 670.

The following application of this method to a typical ship-frame problem has been worked out by R. A. Cummings, Jr., Jun. Am. Soc. C. E. This problem considers the member around the bilge as an arch, with its end tangents free to turn a certain distance depending on the stiffness of the other members framing into it, as well as on the applied loads. It was simplified by the assumption of uniform stiffness throughout the length of the arch axis, and also by the fact that, although the ends here are free to twist, they will not have relative motion. These facts eliminate $\frac{l}{I}$ as a factor in the arch solution, and also eliminate R as an unknown to be solved for in the simultaneous equations. The four unknowns, S_B, S_C, S_D, and S_E, are obtained by the solution of four simultaneous equations for the joints of the frame, B, C, D, and E, respectively. Each of these equations expresses the statically determinate condition, that the summation of the tendencies of all the moments acting on a joint must equal zero.

Fig. 30 shows a diagram indicating the clear or effective span of the members, and Table 3 gives the calculation of the end bending moments of all the members for the condition where all the values of S are zero, which is the fixed-beam moment for the straight members and the hingeless-arch end moments for the arch member, AB.

In Fig. 30, for the lengths of members take the clear span and not the distance from center to center of the supports.

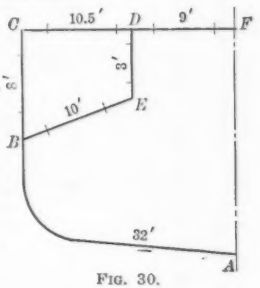

FIG. 30.

Find $\frac{I}{l}$ for all members, and express K in terms of AB, equal to 10,

$$\frac{I}{l} = \frac{d^3}{l} = K$$

$K_{AB} = 10$	$K_{CD} = 3$
$K_{BC} = 4$	$K_{DE} = 10$
$K_{BE} = 3$	$K_{DF} = 4$

Solving these three equations simultaneously gives:

$$M_A = -\frac{K_1 S_A - K_2 S_B + (K_1 + K_2) R_v - K_3 R_H + K_2 \Sigma a \frac{l}{I} M' - K_1 \Sigma b \frac{l}{I} M' + K_3 \Sigma v \frac{l}{I} M'}{K_1 \Sigma b^2 \frac{l}{I} - K_2 \Sigma a b \frac{l}{I} - K_3 \Sigma b v \frac{l}{I}}$$

$$M_B = +\frac{K_2 S_A + K_4 S_B - (K_2 + K_4) R_v - K_5 R_H - K_4 \Sigma a \frac{l}{I} M' + K_2 \Sigma b \frac{l}{I} M' + K_5 \Sigma v \frac{l}{I} M'}{\text{(Same denominator as for } M_A)}$$

$$Fr = +\frac{K_3 S_A - K_5 S_B - (K_3 - K_5) R_v + K_6 R_H + K_5 \Sigma a \frac{l}{I} M' + K_3 \Sigma b \frac{l}{I} M' - K_6 \Sigma v \frac{l}{I} M'}{\text{(Same denominator as for } M_A)}$$

$$K_1 = \left(a^2 \frac{l}{I}\right)\left(v^2 \frac{l}{I}\right) - \left(a v \frac{l}{I}\right)^2 \qquad K_4 = \left(b^2 \frac{l}{I}\right)\left(v^2 \frac{l}{I}\right) - \left(b v \frac{l}{I}\right)^2$$

$$K_2 = \left(a b \frac{l}{I}\right)\left(v^2 \frac{l}{I}\right) - \left(a v \frac{l}{I}\right)\left(b v \frac{l}{I}\right) \qquad K_5 = \left(b^2 \frac{l}{I}\right)\left(a v \frac{l}{I}\right) - \left(a b \frac{l}{I}\right)\left(b v \frac{l}{I}\right)$$

$$K_3 = \left(a^2 \frac{l}{I}\right)\left(b v \frac{l}{I}\right) - \left(a b \frac{l}{I}\right)\left(a v \frac{l}{I}\right) \qquad K_6 = \left(a^2 \frac{l}{I}\right)\left(b^2 \frac{l}{I}\right) - \left(a b \frac{l}{I}\right)^2$$

(NOTE.—All quantities, such as $\left(a^2 \frac{l}{I}\right)$, etc., mean $\Sigma a^2 \frac{l}{I}$.)

These summations may be obtained conveniently by the tabulated form indicated in the problem, and, in any case, are known functions of the shape (a, b, and v), the distribution of stiffnesses, $\frac{l}{I}$, and the loading, M'.

Mr. Maney.

Mr. Maney.

Table 4 contains the complete general expression for the bending moment at each end of every member in the frame. Each of these moments takes the form

$$M_{1-2} = M_F + K\,(3\,R - 2\,S_1 - S_2).$$

M_F, the fixed-beam moment for zero change in end tangent direction, has been calculated, and R has a zero value in these equations, because the action of the frame admits of no relative displacement of the joints. K is a measure of the relative stiffnesses of the various members.

In the member, BA, the end moment, M_{BA}, with zero change of slope, has an arch moment of — 116 000 in-lb. This was calculated in the example under arches. The arch moment sign, as calculated, is negative, which means that the outside arch fibers are tensile. To cause tension on the outside, that portion of the arch near the abutment, B, must rotate counter-clockwise, hence the negative slope deflection sign.

$S_E = +1.106$
$S_D = -2.843$
$S_C = +9.210$
$S_B = -0.106$

Mr. Maney.

The four simultaneous equations necessary for a solution of a stiff frame containing an arch member are indicated in Table 5. Each of these equations states that the summation of the moments at the ends of all members framing into a joint, which occur at the joint, should equal zero. There are as many unknowns to be found (S , S_C, S_D, and S_E) as there are equations.

The coefficients of these unknowns, with their signs changed due to transposition, are indicated opposite the equations at the left of the rows and below the unknown S values indicated at the tops of the columns. The details of the solution and the calculations for the S values are shown in Table 5.

Table 6 contains the calculations for the final values of the moments at the ends of the members. The values of S just found are substituted in the equations shown in Table 4. These final moment values are shown in Table 6 to sum up to zero at the various joints.

TABLE 6.—STIFF FRAME CONTAINING AN ARCH MEMBER.

Final Values of End Moments at Joints.

If $S_B = -0.106$ $S_D = -2.843$

$S_C = +9.210$ $S_E = +1.106$

Then:

Joint.	Member Equation.	Moment. 1 000 in-lb.
B	$M_{BA} = -116.0 - 10\,[(4.50)(-0.106)]$	-111.2
	$M_{BC} = +150.0 + 4\,[-2\,(-0.106) - (+9.210)]$	$+111.0$
	$M_{BE} = 0 + 3\,[-2\,(-0.106) - (+1.106)]$	$+2.7$
C	$M_{CB} = -100.0 + 4\,[-2\,(+9.210) - (-1.106)]$	-173.3
	$M_{CD} = +220.0 + 3\,[-2\,(+9.210) - (-2.843)]$	$+173.3$
D	$M_{DC} = -220.0 + 3\,[-2\,(-2.843) - (+9.210)]$	-230.6
	$M_{DF} = +162.0 + 4\,[-2\,(-2.843) - 0]$	$+184.8$
	$M_{DE} = 0 + 10\,[-2\,(-2.843) - (+1.106)]$	$+45.8$
E	$M_{ED} = 0 + 10\,[-2\,(+1.106) - (-2.843)]$	$+6.3$
	$M_{EB} = 0 + 3\,[-2\,(+1.106) - (-0.106)]$	-6.3
F	$M_{AB} = +3\,527 - 10\,[0.77\,(-0.106) + 0]$	$+3527.8$

On Fig. 31 the load line of the arch is shown as a part of two force polygons. The first has a pole which is arbitrary and is determined by any statically determinate condition where the end forces or rays pass through the ends of the axis. The second or correct pole,

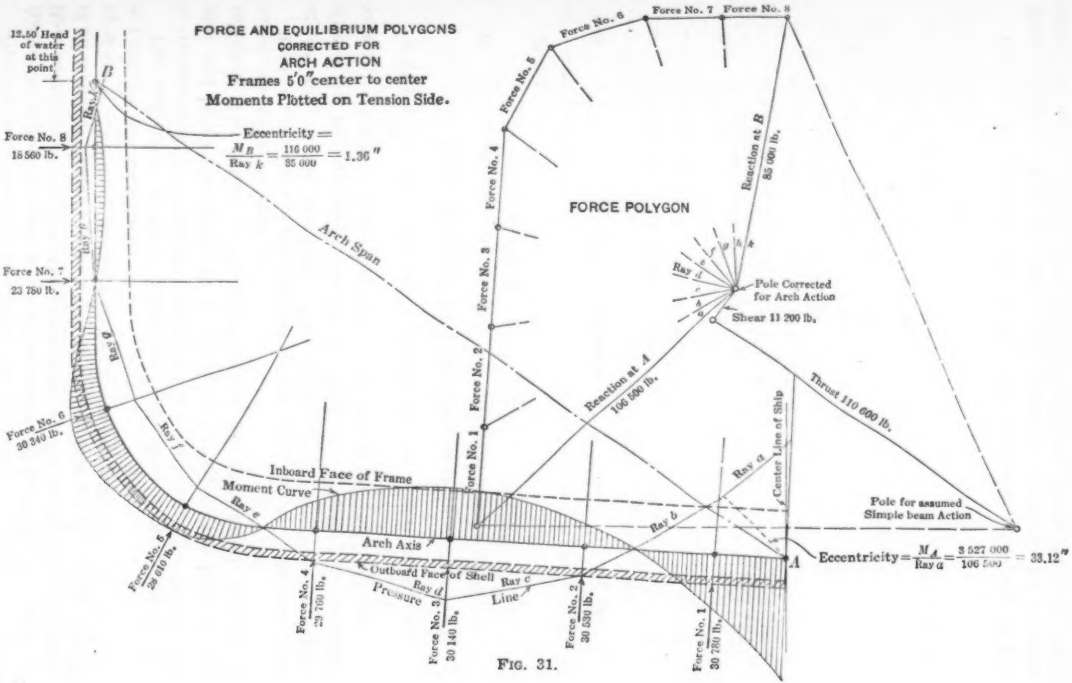

FIG. 31.

Mr. Maney.

which determines the final forces acting on the arch, is found by correcting for M_A, M_B, and Fr. The final pressure line may then be drawn, which will check the calculated final moments on the arch member, AB. Mr. Maney.

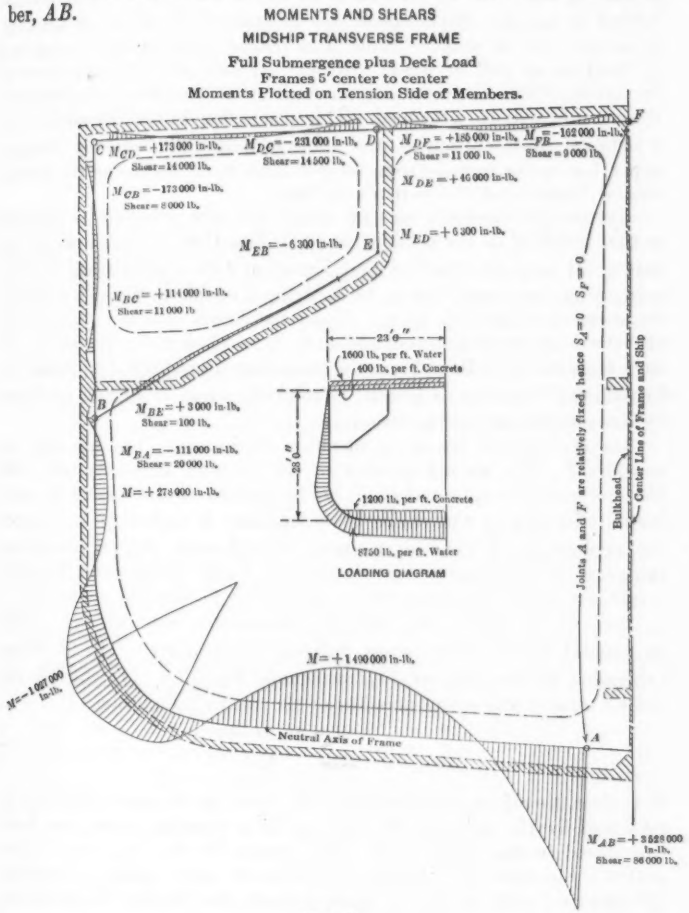

FIG. 32.

Fig. 32 contains sketches indicating the loading for the whole frame, and the final moments throughout the frame, plotted on the tension side of the axis of the members. The shear values are also indicated.

Mr. Burr.

WILLIAM H. BURR,* M. AM. SOC. C. E. (by letter).—This interesting paper is devoted to the establishment and application of what is stated to be a new principle in the determination of stresses and strains in that class of structures in which the axes of members are subject to angular displacement due to stresses of flexure or bending, as arched ribs or simple beams, and trusses with members subjected to bending as well as direct stresses. If any new principle leading to simpler forms of treatment for such structures can be established, it certainly will be welcomed. This discussion is not intended to be a detailed consideration of the subject matter of Professor Swain's paper, but rather to make some simple suggestions regarding the fundamental features of the author's analysis.

Apparently the basic idea on which the new principle is founded is that involved in the establishment of Equations (3) and (4) of the paper. It is to be observed that Equation (3) is established by first using a unit moment, that is, by applying a couple to the given section the moment of which is unity. Under the action of that unit moment, the stress of tension or compression, r, is produced. Equation (3) then legitimately follows from the preceding unnumbered equation, by introducing "(change of length)" due to the stress or stresses produced by the actual loads on the structure.

Let the case of beams or members subjected to bending only be considered. The second member of the author's Equation (3), with the summation sign removed, is to be applied in succession to each section throughout the entire beam, making it necessary to suppose the application of the unit moment to each such section, otherwise, the proper proportionate relation between r and "(change of length)" would not exist. On page 625 of the paper, however, a value of r is written, which results from the application of a moment, M_r, which, in general, has a value quite different from unity. The resulting expression for the angular displacement is Equation (1), which is the second term of the second member of the author's Equation (4):

$$\alpha = \sum \frac{M_s M_r \, d\, l}{E\, I} \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

It is clear, therefore, that the analytical error due to using the stress, r, produced by the moment, M_r, instead of a moment unity, has been introduced in the analysis. In other words, the M_r appearing in the author's Equation (4) should be considered unity, making Equation (1) identical with the old standard formula for angular displacement, which will be recognized at once in Equation (2):

$$\alpha = \sum \frac{M\, \Delta\, l}{E\, I}; \text{ or } \int \frac{M\, d\, x}{E\, I} \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

* New York City.

Mr. Burr.

The results of this analytic error can be pointedly shown by the following two illustrations. In Equation (9), of the paper, the author makes an application of the "new principle" to a beam simply supported at each end and carrying a load at any point, the expression for the angular rotation or displacement being taken at the right-hand end of the beam. The moment, M_r, varies uniformly from unity at the right-hand end of the beam to 0 at the left-hand end. If the load, P, is placed at the center of the span, the angular displacement at the right-hand end of the beam becomes:

$$\alpha_1 = \frac{P\,l^2}{16\,E\,I} = \frac{\frac{1}{2}\,P\left(\frac{l}{2}\right)^2}{2\,E\,I} \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Each half of such a beam is a cantilever, loaded at its free end with $\frac{1}{2}\,P$, the fixed end of the cantilever being at the center of span of the beam. The angular displacement of the free end of such a cantilever in reference to its fixed end may be found by taking one-half of α_1, given by Equation (3), for the reason that the summation or integration shown by Equation (3) covers the entire beam, the length of which is twice that of the cantilever. This will make the angular rotation for the free end of the cantilever shown by Equation (4), which is one-half only of the correct value shown by the author's Equation (7):

$$\alpha = \frac{\alpha_1}{2} = \frac{\frac{1}{2}\,P\left(\frac{l}{2}\right)^2}{4\,E\,I} \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

This half value is due to the author's M_r uniformly decreasing from unity to 0. If M_r were displaced by the moment unity, the true value of angular rotation for the free end of the cantilever would result at once.

Again, the author's method may be used to determine the work expended in bending a beam subjected to loading at right angles to its axis. The stress, s, due to bending only, is given in the second term of the second member of the third unnumbered equation preceding Equation (4) of the paper. That value substituted in the author's Equation (3), after writing da for A and dl for l, will give Equation (5):

$$\alpha = \sum \int \frac{r\,M_s\,y\,d\,l}{E\,I} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

The value of r is:

$$r = \frac{M_r\,y}{I}\,d\,a \quad \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Equation (5) may then be written:

$$\alpha = \sum \int \frac{M_s\,M_r\,(y^2\,d\,a)\,d\,l}{E\,I^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

Mr. Burr. The expression, $\int y^2 \, d\,a$, is, of course, the moment of inertia, I, of the cross-section of the beam. Hence, Equation (7), and also Equation (1), may be written:

$$d\,\alpha = \frac{M_s \, M_r \, d\,l}{E\,I} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

The work performed throughout the entire beam will then be shown by Equation (9):

$$\text{Work performed} = \int \frac{M_s \, d\,\alpha}{2} = \frac{1}{2\,E\,I} \int M_s^2 \, M_r \, d\,l \ldots\ldots (9)$$

The correct usual expression for the work performed in bending a beam, that is, the resilience, is as shown in Equation (10):

$$\text{Work performed} = \frac{1}{2\,E\,I} \int M_s^2 \, d\,l \ldots\ldots\ldots\ldots (10)$$

Equation (9), therefore, is correct only when M_r is unity.

Although the preceding criticism relates only to members or beams subjected to flexure, obviously the use of the author's Equation (3) is limited in its applications to those cases only in which the stress, r, is produced by the application of a couple with a unit moment to the sections covered by the summation.

It may be justly urged that since the moment, M_r, must be considered unity, its use as an analytic device is superfluous and unnecessary. So far as members subject to flexure only are concerned, nothing could be simpler or more direct in application than the old and standard formula given by the writer's Equation (2). This formula has been used, for many years, for angular displacement or rotation of the longitudinal axis of a bent member, especially in connection with the treatment of arched ribs.

Just what is meant specifically by the "new principle" is not obviously clear. The use of analytic expressions for the work performed in stressing both beams and pieces subject to direct stresses of tension or compression in the determination of deflections and for other similar purposes, is quite old. It would also seem to be much more simple to write the author's Equation (4) in correct form, by a direct equation between the external work performed and the sum of the two expressions for work, one covering members subject to direct tension or compression, and the other covering those subject to bending. This would render superfluous and eliminate the analytical work preceding Equation (4).

In passing, the surprising statement of the author, following his Equation (14), may be noticed. In referring to that equation, he writes, "which is the most general form of the Theorem of Three Moments." The most general form of the "Theorem of Three Moments", as is well known, provides for a variable moment inertia, a curved or broken center line of beam or truss, and other features

which are not even recognized in Equation (14). In fact, that equation is really a highly restricted form of equation expressing the "Theorem of Three Moments." Mr. Burr.

A. C. JANNI,* M. AM. SOC. C. E. (by letter).—It has been already remarked by others that the conception of the angular displacement, or rotation, of a cross-section of a solid body, as well as the derivation of the relative formula, is not new; indeed, it is as old as the conception of the linear displacement of a point of a solid body, together with its relative formula. The claim to novelty in this case, therefore, seems to be quite out of place. Any good textbook will give some method of deriving this formula from the general expression of the "virtual work", either by the theorem on the "derivative of work", or by invoking the principle of "least work." Mr. Janni.

Of course, in using this formula, any book of higher engineering does not need to explain fully its origin, for it is assumed that whoever consults such books, is already familiar with the theory by which this formula has been worked out. That this is the logical assumption of the authors of such works is noted, for instance, in Grimm's book on Secondary Stresses, which is one of the only two mentioned by Professor Swain in his paper, as having been consulted by him on this matter, and which would justify his belief that the principle treated by him is new. In Chapter VII of this book, the author, speaking about the principle of "virtual work", states "with which the reader is supposed to be familiar."

That Professor Swain has been able to work out from this established formula a few plain cases of equations of equilibrium is not to be wondered at, for the derivation of the formula itself was worked out long ago from these equations, as any student in any engineering school should know.

After these considerations, there does not seem to be any necessity or use for the Profession to go into details and analyze the interpretation as given by Professor Swain to an already established principle and formula, for, at the present state of the science, this interpretation, at its best, would hardly be used by a modern engineer, for it is obsolete, as will be shown later by comparison.

Although the solution of this problem, considered by itself, has a doubtful practical value in most cases of equilibrium, still it will be demonstrated that by the theory of the "ellipse of elasticity", it is possible to obtain the desired solution in a manner which leaves no doubt as to the superiority of modern methods over the old ones. A few remarks will precede the exposition of the method.

To any elastic body there corresponds a certain quantity, or coefficient, called "elastic weight", which is a function of its length, its cross-section, its moment of inertia, and of the modulus, E, of the

* New York City.

Mr. Janni.

material.* It will be shown, in each case, how this elastic weight is to be computed.

The "elastic center" is the center of gravity of the elastic weights of a given body. If the elastic weight of a certain elastic system is concentrated, or applied, at the elastic center of the body, and a force, P (Fig. 33), is acting on the free end of this system, the following mathematical truth can be demonstrated:

The angular rotation α, of the free end of the elastic body, with respect to its fixed end, is given by the force times the static moment of the elastic weight with respect to the line of action of the acting force. That is, if P (Fig. 33) is the force applied, G, the elastic center and its value as well, and d, the distance between the line of action of P and the point G at which the value, G, is applied, then:

$$\alpha = P \times G \times d.$$

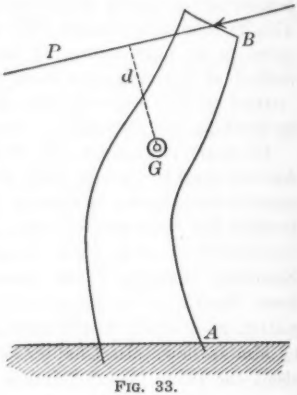

FIG. 33.

Consistent with brevity, a few cases will be shown, which will represent fairly the solution for almost all possible cases in practice.

Attention is called to the brevity, uniformity, and directness of this method, as well as to the very elementary kind of operations involved, in order to obtain the result.

Case 1.—Let AB (Fig. 34) be the geometrical axis of a beam, fixed at one end, A, and free at B, and let P be a vertical force applied at B. The inclination, α, of the tangent at B' is desired.

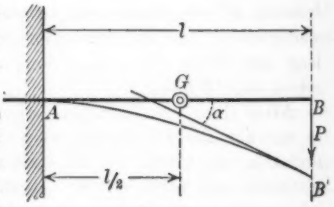

FIG. 34.

* The geometrical axis of a solid, usually, is not a straight line, and its cross-section is not constant. In this case, the solid is to be divided into parts, and the elastic weight of each part, or element, is to be computed separately, as will be shown later.

These elementary elastic weights are designated, usually, by the letter, w, with a numerical progressive index, and each is supposed to be applied at the center of gravity of its own element.

The elastic weight of the whole body is the summation of these elementary elastic weights.

Considering these w's as forces applied to the various centers of gravity, the position of the center of gravity of the entire system of forces, w's, may be determined.

This point is called the "elastic center", and the whole elastic weight is supposed to be applied at this center.

The position of this point, usually, is indicated by the letter, G, as is its value, so we have:

$$w_1 + w_2 + w_3 + \ldots + w_n = \Sigma_1^n w = G.$$

Mr. Janni.

Assuming that:

E = modulus of elasticity,

I = moment of inertia = constant, and,

A = area of cross-section = constant,

then the elastic weight of the whole beam is given by $G = \frac{l}{E\,I}$, and if it is supposed to be applied at G (the center of gravity of the elastic system), by the principle previously stated, we obtain:

$$\alpha = P \times \left(\frac{l}{E\,I} \times \frac{l}{2}\right) = \frac{P\,l^2}{2\,E\,I}$$

which result solves the problem.

Let us suppose now that the cross-section, A, is not constant, as is shown in Fig. 35; then, in order to take this variation into account, the geometrical axis, AB, will be divided into a number of parts, such that each of them may be considered, without sensible error, as a prism.

Then, find the $\frac{\Delta\,l}{E\,I} = w$ for each of these parts and, assuming that each w is a vertical force applied correspondingly at 1, 2, 3, ..., determine the position of their center of gravity (elastic center), G.

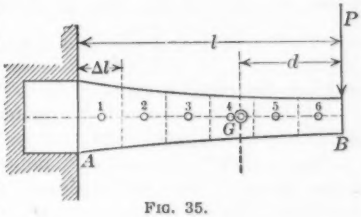

FIG. 35.

Now, remembering that the total elastic weight, G, is to be considered as applied at G, and remembering, also, the previously mentioned principle, we may write:

$$\alpha = P \times G \times d$$

where:

$$G = w_1 + w_2 + \ldots + w_6 = \Sigma^6_1\, w$$

Case 2.—Angular Rotation of the Free End of a Three-Member Frame.—Let Fig. 36 represent a three-member frame, comprising a girder supported at its ends, A and B, by posts, CA and DB, the girder connections at A and B being rigid, the post, CA, rigidly fixed at C, and the post, DB, on rollers at D.

Let us assume, as is usual, that the system has no dead load, and let us remove the ground support at D. Assuming, also, that E is the modulus of elasticity, and I is con-

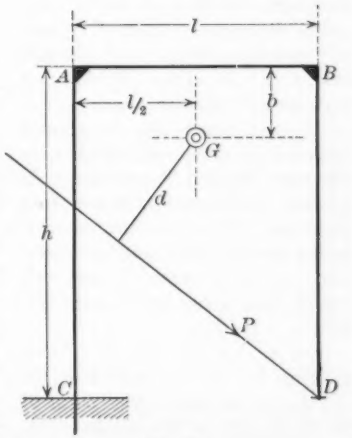

FIG. 36.

Mr. Janni

stant for all three members, then the elastic weight for each post is given by $\frac{h}{E\,I}$, and that of the girder by $\frac{l}{E\,I}$; therefore, the total elastic weight of the system will be:

$$G = \frac{l}{E\,I} + 2\,\frac{h}{E\,I} = \frac{1}{E\,I}\,(l + 2\,h)$$

The elastic center, G, of the three elastic weights, each of which being applied at the middle point of the corresponding member (see the first problem of Case 1), for the cross-section, A, is supposed to be constant, will lie on the vertical axis of the symmetry of the frame, and at a distance, b, from AB, given by:

$$b = \frac{2\,\frac{h}{E\,I} \times \frac{h}{2}}{\frac{1}{E\,I}\,(l + 2\,h)} = \frac{h^2}{l + 2\,h}$$

A force, P, applied at D, will cause a rotation of the section, D, which, by remembering the previously stated principle, is given by:

$$\alpha = P \times \left[\frac{1}{E\,I}\,(l + 2\,h) \times d\right] = \frac{P\,.\,d}{E\,I}\,(l + 2\,h)$$

which is the result sought.

At this point, it seems to the writer that some remarks may be made, which are rather interesting.

Suppose that the force, P, revolves about D, then the angle, α, will vary with the distance, d. If, therefore, the line of action of P passes through G, then d is zero and, consequently, $\alpha = 0$. In this case, then, the section, D, does not perform any angular rotation.

In the previously mentioned theory, it is demonstrated that, in this case, Section D performs only a linear displacement, in a certain direction. The amount of this linear displacement and its direction can be determined, but it is not thought necessary to enter this field any further.

Let us suppose that the force, P (Fig. 37) is not applied at the end D, but at some other point of the frame, say, at the middle point, N, of AB. Then this force, as far

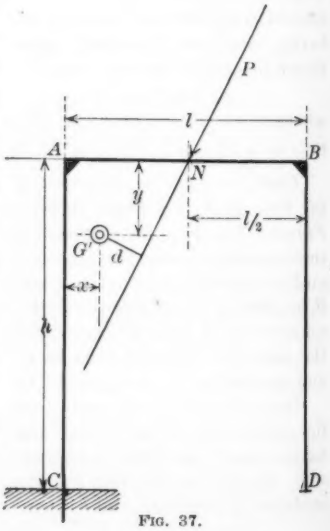

FIG. 37.

as internal stresses in the frame are concerned, has no effect on the half frame at the right of force, P, that is, on NBD. Mr. Janni.

In this case, we determine the following elastic weights:

$$\text{Elastic weight of } A\ C = \frac{h}{E\,I}$$

$$\text{“ “ “ } A\ N = \frac{l}{2\,E\,I}$$

$$\text{Total elastic weight} = \frac{1}{E\,I}\left(h + \frac{l}{2}\right).$$

The position of the center, G', is, evidently, given by:

$$x = \frac{\frac{l}{2\,E\,I} \times \frac{l}{2}}{\frac{h}{E\,I} + \frac{l}{2\,E\,I}} = \frac{l^2}{2\,(2\,h + l)};\ y = \frac{\frac{h}{E\,I} \times \frac{h}{2}}{\frac{h}{E\,I} + \frac{l}{2\,E\,I}} = \frac{h^2}{2\,h + l}.$$

Therefore:

$$\alpha = P \times \left[\frac{1}{E\,I}\left(h + \frac{l}{2}\right) \times d\right] = \frac{P\,d}{E\,I}\left(h + \frac{l}{2}\right).$$

Here, also, if the line of action of P passes through G', the section, N, and, consequently, the end, D, of the frame does not perform any rotation, but only a linear displacement.

Incidentally, by inspecting Figs. 36 and 37, it may be seen that it is always possible to regulate the force, P, in each case, as to its intensity and line of action, so that the rotation, α, of Section D is the same in each case.

It can be seen also that by the use of this principle in the solution of problems of this kind, apart from the fact of the very elementary operations required, one gets also an absolute and easy control of the behavior of the elastic system.

Case 3.—Let AB (Fig. 38), represent an arched solid, the law of generation of which may be any, and let us suppose that it is fixed at B and free at A (the terminal section of the solid). The angular rotation of the end section, A, is required, in the hypothesis that a force, P, acts on the whole solid at A (this force may be imagined as acting on A, away from A, but rigidly connected with it). The solid is divided into any number of parts (seven in this case), and the corresponding seven elastic weights are computed.

Imagine that these elastic weights, $w_1 = \frac{\Delta\,l}{E\,I_1}, w_2 = \frac{\Delta\,l}{E\,I_2}, \ldots w_7 = \frac{\Delta\,l}{E\,I_7}$, are forces, each applied at the corresponding center of gravity 1, 2, 3, . . . 7 of the voussoir or element, and determine the position, G, of the elastic center (center of gravity of the elastic weights).

Mr. Janni.

Then, if P is the acting force, the angular rotation, α, of A, by making $G = \Sigma_1^7 w = w_1 + w_2 + \ldots + w_7$ is given by:

$$\alpha = P \times (G \times d) = P \times G \times d,$$

which value solves the problem.

If P' is the force applied to the elastic body then, as in Case 2, the terminal section, A, will not perform any angular rotation, but a linear displacement, the amount and direction of which can be determined, as previously stated.

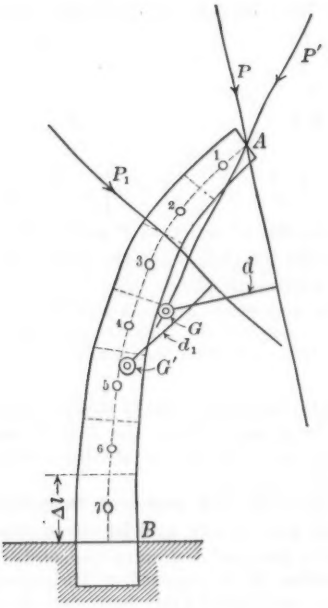

FIG. 38.

In the case in which the force applied is P_1, then, similarly, as in Case 2, the position of G' must be determined, as well as its value; remembering, however, that, in this case, the elastic weights to be omitted are $w_1 = \frac{\Delta l}{E I_1}$ and $w_2 = \frac{\Delta l}{E I_2}$, for the force, P_1, has no direct effect on the two voussoirs, 1 and 2.

Mr. Janni.

The position, G', the center of gravity of the system 3, 4, 5, 6, and 7, being determined, and the value of d_1 found, we will have:

$$\alpha = P_1 \times (G' \times d_1) = P_1 \times G' \times d_1$$

which solves the problem.

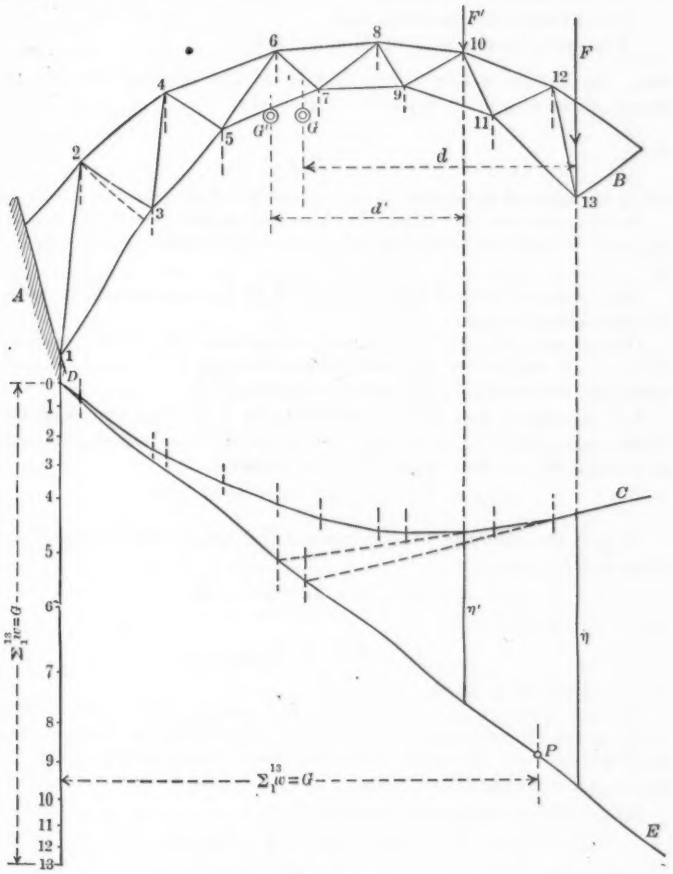

FIG. 39.

Case 4.—Finally, let AB (Fig. 39) be a latticed arch, having the end A fixed and the end B free. Let us find the angular rotation of B when a force acts on this elastic system.

Mr. Janni.

In the solution of this problem, the most general method will be used.

If we put:

l = length of 1-3,
r = distance between Point 2 and Line 1-3,
E = modulus of elasticity, and,
A = cross-section area of Member 1-3,

then, the elastic weight corresponding to the Member 1-3, by the theory of the ellipse of elasticity, is given by:

$$w^2 = \frac{l}{E\ A\ r^2}$$

which is supposed to be applied at its corresponding pole, 2.

In the same way, the other elastic weights of the system, w_1, w_3, ... w_{13}, may be computed and applied to the corresponding poles, 1, 3, ... 13.

Now, draw a vertical line and lay off on it, at a convenient scale, all these elastic weights.

Choose any pole, P, at a distance from this vertical line equal to $\Sigma_1^{13} w = G$, and on the verticals passing through 1, 2, ... 13, construct the corresponding funicular polygon, CDE.

Let us suppose now that a vertical force, F, is acting at B on the whole system, then, as has been previously stated, the rotation performed by Section B is to be computed by the formula:

$$\alpha = F \times (G \times d) = F \times G \times d$$

If η is the intercept on the vertical line of F, determined by the polygon, CDE, then:

$$G \times d = \eta \times (\Sigma_1^{13} w = G)$$

therefore, we may write:

$$\alpha = F \times G \times \eta \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

which solves the problem.

Let us suppose, now, that the force F' is acting on this system, then omitting the elastic weights, w_{11}, w_{12}, w_{13}, on which the force, F', has no direct bearing, the new system will have a new elastic center, G', and its value will be $G' = \Sigma_1^{10} w$.

Identically, as before, we will have:

$$\alpha = F' \times (G' \times d') = F' \times G' \times d'$$

and, if η' is the intercept, as shown in Fig. 39, then:

$$G' \times d' = \eta' \times (\Sigma_1^{13} w = G) = \eta' \times G$$

therefore:

$$\alpha = F' \times G \times \eta' \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Mr. Janni.

By inspecting Equations (1) and (2), it may be seen that there is no necessity, in any case, to determine the position of the elastic center, but that the construction of the polygon, *CDE*, is sufficient for the solution of the problem, no matter what the point is on which the external force is supposed to act. That is, we may write the expression, α, in its most general form, thus:

$$\alpha = \text{Acting force} \times \text{Total elastic weight} \times \text{Intercept on the vertical of the acting force by the funicular polygon, } CDE.$$

This kind of a problem could hardly be more elegantly and simply solved than by the use of this modern theory.

Mr. Eddy.

H. T. EDDY,* Esq. (by letter).—There is a certain limitation to Mr. Maney's method which seems to make his arch analysis inapplicable to the transverse frames of ships; and even were this obstacle removed in some way, the moment of inertia of reinforced concrete arch sections suffers such discontinuous changes under stresses, due to combined bending and compression, depending on which of these two kinds of stress predominates, that the method would require radical emendation to make it afford a suitable basis for investigating the design of concrete ships.

The limitation just mentioned may be expressed by stating that the method is necessarily restricted to cases where every one of the applied forces of the arch loading acts in a direction perpendicular to the line, *AB*, joining the ends, *A* and *B*, of the member which acts as an arch. That this is necessarily so is evident from the fact that the moment, *M'*, of all the applied forces, including the reactions of the supports, but excluding the restraining moments at the supports, must be calculated, as is correctly stated by Mr. Maney, on a statically determinate basis. This requires that the magnitudes of both the opposing thrusts, F_A and F_B, acting along *A B*, at *A* and *B*, respectively, shall be known.

These thrusts, however, are statically indeterminate in case there is a component, *P*, of any force which is applied to the arch rib at any point that acts in a direction parallel to *AB*, since, in that case, the algebraic sum of the reactions along *AB* that hold *P* in equilibrium is $F_A + F_B = P$, in which the actual magnitudes of F_A and F_B are statically indeterminate, not only for an arch, but for a straight member as well. For it is evident that a force, *P*, applied longitudinally to a straight piece, *AB*, at some point, *Q*, intermediate between its extremities taken as fixed, will awaken reactions at *A* and *B* which are not statically determinate, but are dependent on the relative length and elasticity of the segments, *QA* and *QB*. This is also true of an elastic arch, *AQB*.

* Minneapolis, Minn.

Mr. Eddy.

In general, the thrusts, F_A and F_B, at the supports are statically determinate only in case $F_A + F_B = 0$, that is, in case no one of the applied forces has a component parallel to AB.

However, since hydraulic pressures act normal to the exterior surface of a ship, any curved member of a transverse frame functioning as an arch rib and subjected to these pressures must be subjected to components of those pressures, which act along the line, AB, joining its extremities. Hence, the proposed method based on zero pressures parallel to AB is inapplicable to curved members of ship frames.

Just how this limitation restricts the proposed analysis may be made more clear by the following discussion of the principles involved in establishing and interpreting Mr. Maney's Equation (1), which is an expression in algebraic form of the fundamental principles of the loaded elastic arch with level supports, as first made public by the writer in his paper on "Certain New Constructions in Graphical Statics."*

In considering arch action in general for vertical loads, it may be stated that when the axis of the arch rib coincides in position and direction with the line of resultant pressures due to all the applied forces—which line is identical with the equilibrium polygon of those forces—then the structure constitutes an equilibrated arch, as it is called by Rankine, and the arch action of a rib of this shape provides, by reason of its shape alone, all the resisting moment that is required in order to hold in equilibrium the moments of the applied forces, and no bending moment whatever is exerted by the arch rib itself in resisting the applied moments. The entire stress in the rib in this case consists of direct compression along its axis. An equilibrated arch coincides with a catenary curve of the loads placed in an upright position.

Let A and B be the points of support on the axis of an arch rib, AQB, as in Fig. 29, in which AB is horizontal and Q any point on the curved axis. If the point, Q, does not also lie on the equilibrium polygon of the applied forces corresponding to the actual thrust, F, of the arch, then this is not an equilibrated arch, because the curved axis of the arch deviates at this point, Q, from the equilibrium polygon and, consequently, the arch rib itself must sustain some bending moment, M, and thus furnish part of the moment that resists the total moment, M', due to the applied forces.

* Read before the American Association for the Advancement of Science at Buffalo, N. Y., in 1876, and, later, published in the *American Journal of Mathematics*, Vol. I, No. 1, and in *Van Nostrand's Engineering Magazine*, and republished in the writer's book entitled "Researches in Graphical Statics", New York, 1878.

Let Q' be the point where the vertical at Q cuts the equilibrium polygon, and Q'' the point where it cuts AB; and let r = the total rise of the arch, and $QQ'' = vr$, then: Mr. Eddy.

$M' = F \times Q'\ Q''$ = the total moment at Q of all the applied forces as found for a simple beam, AB, that is, the moment due to all the forces and reactions except end moments.

$M = F \times Q'\ Q$ = that part of the moment M' resisted by the bending moment in the arch rib.

$Fvr = F \times Q\ Q''$ = that part of M' resisted by arch action by virtue of the thrust, F, along AB, and the equal horizontal component of axial compression at Q.

$Fvr + M$ = total resisting moment due to arch action and to the bending moment in the rib.

Let $AB = L$, $AQ'' = aL$, and $BQ'' = bL$, and let M_A and M_B be the restraining moments at A and B, respectively. Then, aM_B and bM_A are the resisting moments at Q due, respectively, to M_B and M_A.

When the applied forces are perpendicular to AB, the conditions of equilibrium of the arch rib, AQB, evidently require at every point, Q, that the sum obtained by adding the bending moment, M, of the rib itself to the moment, Fvr, representing the arch action, shall be equal to the total statical moment at that point due to all the forces applied to the arch, including not only the vertical loads and the reactions of the supports, but also the effects of the restraining moments at A and B.

Hence, we obtain Mr. Maney's Equation (1), namely,

$$M + Fvr = M' + aM_B + bM_A$$

in which the intrinsic sign of F has been reversed for convenience.

The total statical moment, M', may be taken to consist of two parts, as follows: One part due to the loads and the vertical components of the reactions which may be constructed by drawing the equilibrium polygon for a simple beam supported at the ends with a pole distance = F, and carrying the applied loads. The vertical ordinate at any point, Q, of this polygon multiplied by F will give the moment at Q of the loads and the vertical components of the reactions at A and B. The other part of M' is Fvr, the moment of the horizontal component of either reaction. Since, however, both sides of Equation (1) include the same quantity, Fvr, the first side explicitly, and the other side implicitly in M, they might be expressed so as to cancel each other, and it is, consequently, wholly immaterial what value may be assigned to F, the horizontal component of the

Mr. Eddy.

reaction at either support, or, what is the same thing, the direction of one reaction may be arbitrarily assumed provided all the loads act perpendicularly to AB, for Equation (1), in fact, has to do only with the moment of the vertical forces.

As already stated, another question of fundamental importance in reinforced concrete under combined compression and bending is a correct method of calculating the value of the moment of inertia of any composite cross-section, especially at points where the applied moments are large.

The value of I in a combination of concrete and metal depends, not on the area of the concrete and steel alone, but on the condition of stress normal to the section. If the condition of stress is that of simple flexure, with no longitudinal thrust, then I depends entirely on the steel and its position in the matrix, together with that part of the concrete which is under compression. If, however, the entire section is under compression, then I depends on the total area of the concrete and the area of the steel combined.

As an example, consider the moment of inertia of a column supporting a floor. If the load on the column is such that the total area of the concrete is under compression, then this total area enters into the moment of inertia of the column section and must be taken into consideration in the apportionment of moments between the column and the floor. Whereas, if the load is insufficient to cause the column to be under compression throughout its full area, that part of the section of the concrete which is under tension, does not enter into the determination of the moment of inertia, but must be disregarded entirely. Deflections may vary in such constructions nearly 100% with the variations of the moment of inertia of the same cross-section of metal and concrete depending entirely on the state of longitudinal stress in the columns. Under Mr. Maney's discussion, no attention is paid to this important matter, and the validity of his analysis must depend on the correctness of the determination of I at the different sections considered, even in cases where the applied loads have no components parallel to AB.

Professor Burr's objections and emendations do not seem to be well taken in his attempt to identify Dr. Swain's formula for the actual rotation, α, which occurs at any section of a piece, due to the loads and restraints to which the whole piece is subjected, with the total change of slope or curvature between two given sections of the piece in accordance with Rankine's formula:

$$i_2 - i_1 = \int_1^2 \frac{M_s \, d\, l}{E\, I}$$

where i_1 and i_2 are the slopes at given sections, A and Q, of a piece, AB.

Mr. Eddy.

It is only in certain particular cases that the change of slope, or the total curvature produced between A and Q, as found by this equation, is the same as the rotation at Q, since they are the same only when the piece is fixed at A in such a manner that no rotation occurs at that point. Then, and then only, do the formulas for slope and rotation give identical results.

If, however, the piece is fixed at A and free at B, then a unit moment applied at Q must be held in equilibrium by a unit-resisting moment at A, and there is a unit-bending moment, M_r, produced by it at every point of AQ, and no bending moment, M_r, in BQ.

It is self-evident, however, that, in Dr. Swain's Equation (5), M_r cannot in general be equal to unity, as Professor Burr asserts, because the limits of the integrations in which it occurs extend, all told, from A to B, although the section where the rotation occurs is at Q, because the integration above for the change of slope extends from A to Q only. In other words, if $M_r = 1$ at all points of AB that would require:

$$\int_A^Q \frac{M_s\, d\, l}{E\, I} = \int_A^B \frac{M_s\, d\, l}{E\, I},$$

where the first member is the change of slope and the second member is the rotation, in case M_r is assumed to be equal to unity.

Hence,
$$\int_A^Q \frac{M_s\, d\, l}{E\, I} = \int_A^Q \frac{M_s\, d\, l}{E\, I} + \int_Q^B \frac{M_s\, d\, l}{E\, I},$$

$$\text{or, } 0 = \int^B \frac{M_s\, d\, l}{E\, I},$$

which is absurd.

The conclusive demonstrations of Castigliano and Müller-Breslau, as shown clearly by Professor Church and Mr. Mensch, in their extended and original elucidations, make it certain that Dr. Swain's formula contains no material error when properly interpreted.

It should be particularly noted that the value of M_r depends on the same restraints and the same manner of support that are effective to determine the distribution of the applied moments that produce the moment, M_s, actually operating.

For example, in a beam of length, $AB = L$, uniformly loaded and rigidly fixed in direction at both A and B, the moment polygon due to a unit couple applied at Q, when $AQ = aL$ and $BQ = bL$, consists of two horizontal lines such that in the segment, AQ, we have $M_r = b$ and, in BQ, we have $M'_r = -a$. The sides of the polygon are straight at the right and left of Q, because the only applied forces in the polygon, the ordinates of which represent M_r, are the forces of a couple of unity applied at Q. The fixity of the ends requires that the positive moment area shall equal the negative area, as they do in this case, namely, $aLM_r = -bLM'_r = abL$.

Mr. Cain.

WILLIAM CAIN,* M. AM. SOC. C. E. (by letter).—Professor Swain published in the *Journal* of the Franklin Institute, for February, March, and April, 1883, a paper "On the Application of the Principle of Virtual Velocities to the Determination of the Deflection and Stresses of Frames", the method being based principally upon the investigations of Mohr and Winkler. It is interesting to note that the author has taken up the subject again after 36 years, and has applied the method to finding the rotation of a section of a beam or truss, under given loading; eventually applying the results to deducing the "Theorem of Three Moments" and in making other interesting applications. The formulas and their applications are sound in theory and are neatly and concisely presented.

It is true, as pointed out by both Professor Church and Mr. Mensch, that the author's Equation (6) is implicitly contained in a theorem of Castigliano,† but the author deserves our thanks for putting it in this definite, explicit form, where no differentiation is called for. The method of the author does not require, as in the "moment area" method, that the beam or frame shall be fixed in direction anywhere, but it does require immovable abutments, and that all the reactions at the abutments, whether due to the loads alone, or to the fictitious couple, shall be included in the forces acting on the structure, which is then taken as a free body, in equilibrium under the loads and reactions, including any restraining couples acting at the abutments.

When these conditions are observed, the author's Equation (6) gives the rotation of a section of a beam or truss when the summation (or integration) covers the whole beam or all the members of the truss. Thus, for the simple beam, Fig. 2, subjected to a load P and a couple, the moment of which is $M = 1$, applied at the right end, the beam is free under these loads with their corresponding reactions. Then, when the integration covers the entire span, Equation (5) gives the rotation (in radians) of a vertical section where the couple is applied. It would be erroneous to apply the method to only a part of the truss, for reasons given later.

By Castigliano's method, where an actual force at the point, acting in the required direction, (or an actual couple at the desired section), is not available, an arbitrary force (or couple) is applied at the point (or section), which is eventually taken equal to zero; then, the partial derivative of the internal work of the structure with respect to the force gives the deflection, at that point, in the direction of the force, and the partial derivative of the internal work with respect to the

* Chapel Hill, N. C.

† The writer first had the pleasure of introducing Castigliano's masterly treatise on "Systèmes Elastiques" to the notice of American engineers in a paper, published in *Transactions*, Am. Soc. C. E., Vol. XXIV, p. 265, April, 1891. In this paper, some original demonstrations of the method of deflection and least work were given, besides a general résumé of Castigliano's fundamental theories and methods, with some applications.

moment of the couple, supposed applied at a section, will give the rotation of that section. Mr. Cain.

Thus, in the case of arches subjected to vertical or inclined loads, there are introduced at a point on the axis a horizontal force, w, a vertical force, w', and a couple of moment, m; then, if L is the internal work of the arch, expressed in terms of w, w', and m and the given loads, then, taking partial derivatives and, in the end, making w, w', and m equal to zero,

$$\frac{dL}{dw} = \text{horizontal deflection of point;}$$

$$\frac{dL}{dw'} = \text{vertical deflection of point;}$$

$$\frac{dL}{dm} = \text{rotation of section at point,}$$

all for the actual loads only.

In the case of a long column subjected to an inclined load at the top, eccentrically applied, the general solution is effected with the use of only the two loads w and w'. In other cases, only one load or one couple may be used. To give an illustration of Castigliano's method, take the case of the simple beam, shown in Fig. 3, where a load, P, is applied at a distance, a, from the left abutment and an arbitrary couple, which is taken left-handed, is supposed applied to the beam at the load, say, by means of a bar bolted to the beam. If M_1 is the moment of the couple applied at P, its left reaction acts up and equals $\frac{M_1}{l}$, and its right reaction acts down and also equals $\frac{M_1}{l}$.

Call M the moment of all forces from the left abutment to a section x ft. from the left abutment, or x_1 ft. from the right abutment.

$$o < x < a,\ M = P\frac{l-a}{l}x + M_1\frac{x}{l};\ \therefore \frac{dM}{dM_1} = \frac{x}{l}$$

$$o < x_1 < (l-a),\ M = P\frac{a\,x_1}{l} - M_1\frac{x_1}{l};\ \therefore \frac{dM}{dM_1} = -\frac{x_1}{l}.$$

Now, neglecting shear, the internal work for the beam is given by the well known formula

$$L = \frac{1}{2}\int_0^l \frac{M^2}{EI}\,dx$$

whence the rotation of a vertical section at the load is

$$\alpha_1 = \frac{dL}{dM_1} = \int_0^l \frac{M}{EI}\,\frac{dM}{dM_1}\,dx.$$

On putting $M_1 = 0$ in the values of M given above and then substituting the values of M and $\frac{dM}{dM_1}$ pertaining to the parts of the beam to

Mr. Cain.

the left and right of the load and integrating between the limits $x = 0$ and $x = a$ for the left part, and between $x_1 = 0$ and $x_1 = (l - a)$ for the right part, we are conducted to the integral given by the author, and thus to his value

$$\alpha_1 = \frac{P\,a\,(l-a)\,(2\,a-l)}{3\,E\,I\,l}.$$

As this is negative, the rotation of a vertical section at the load is in the opposite direction to that of the couple, or clockwise. Since the influence of shear on bending was neglected, this value of α_1 likewise gives the slope of the elastic curve (in radians) at the load, which is thus downward to the right.

It is seen that the values of $\frac{d\,M}{d\,M_1}$ above are the same for any value of M_1 and therefore for $M_1 = 1$, in which case the moments due to this couple of moment 1 are exactly the values given by the author, so that $\frac{d\,M}{d\,M_1} = M_r$ as defined by the author. In fact, this is generally true for all cases, since M is always a linear function of M_1 for any structure, hence the author's Equation (5) is identical with Castigliano's formula

$$\alpha = \int \frac{M}{E\,I}\,\frac{d\,M}{d\,M_1}\,dx$$

for any beam, straight or curved.

As to the more general formulas for Δ and α, Professor Church, in his discussion, has so thoroughly pointed out the equivalence of the author's and Castigliano's formulas, that it seems superfluous to make any further comment thereon.

Where an external couple acts at the required section, it is not necessary to add the arbitrary couple. Thus, for the beam supported at the ends and subjected only to a couple, M_2, at the right end, Fig. 6, we have

$$M = \frac{M_2}{l}\,x; \quad \therefore \frac{d\,M}{d\,M_2} = \frac{x}{l}$$

and the rotation of a vertical section at the right end is

$$\alpha = \int_0^l \frac{M}{E\,I}\,\frac{d\,M}{d\,M_2}\,dx = \frac{1}{E\,I}\int_0^l \frac{M_2\,x^2}{l^2} = \frac{M_2\,l}{3\,E\,I}.$$

Since α is positive, the rotation is in the direction of that of the couple, or counter-clockwise. The same final result would be obtained by the use of an arbitrary couple at the right end, but the work is slightly greater.

Mr. Mensch, in his comprehensive discussion, premises that the theory, in its most general form, is based upon the law that Mr. Cain.

$$\text{External work} = \text{Internal work};$$

where "external work" includes that of the loads and reactions (including restraining couples, if any). It is thus evident that the usual formulas are only true for immovable abutments, where the reactions do no work.

It may be well to add that for a simple beam with vertical loads, if the left abutment sinks e ft., its vertical reaction, R, does the work $-R\,e$. The total sinking of any load, P, on the beam with reference to the ground, is made up of two parts, a part, Δ_1, due to the rotation of the straight beam about the right end, from the sinking of the left end e ft.; and a second part, Δ_2, due to the elastic deflection, referred to immovable abutments. Thus, the "external work" in this case is

$$-R\,e + \Sigma\,P\,(\Delta_1 + \Delta_2)$$

where the sum is to be taken for all the loads on the beam. Similarly, the case where both abutments sink can be dealt with. If both abutments sink an equal amount, then the external work is simply equal to $\Sigma\,(P\,\Delta_2)$.

If there is a restraining left-handed couple, the moment of which is M_1, at the left end of a loaded beam and the vertical section there turns α radians to the right, then it is easily shown that the work of the couple is $-M_1\,\alpha$. For gradually applied loads, the reaction and restraining couple will be gradually applied, so that the "exterior work" will be one-half of that given above, or

$$\frac{1}{2}\left[-R\,e - M_1\,\alpha + \Sigma\,P\,(\Delta_1 + \Delta_2)\right]$$

which must be equated to the "internal work"; or, the convenient derived formulas of Mr. Mensch may be applied.

Simply to illustrate the application of the general method, consider again the simple beam shown by Fig. 3, which carries a single load P, distant a ft. from the left abutment. Then, for immovable abutments, if Δ is the deflection at the load for a gradually applied load, the exterior work is $\frac{1}{2}\,P\,\Delta$, which equals the interior work

$$\frac{1}{2}\int_0^l \frac{M^2}{E\,I}\,dx$$

$$\therefore \Delta = \frac{1}{P}\int_0^l \frac{M^2}{E\,I}\,dx,$$

a well known formula.

Mr. Cain.

Here, to the left of the load,

$$M = P\,\frac{l-a}{l}\,x;$$

to the right of the load,

$$M = P\,\frac{a}{l}\,x_1.$$

Therefore,

$$\Delta = \frac{P}{E\,I}\left[\int_0^a \frac{(l-a)^2}{l^2}\,x^2\,dx + \int_0^{l-a} \frac{a^2}{l^2}\,{x_1}^2\,dx_1\right]$$

$$\therefore\ \Delta = \frac{P\,a^2\,(l-a)^2}{3\,E\,I\,l}.$$

To find α, the rotation of a vertical section at the load, pass a section through the beam just to the left of P and supply forces at the section equivalent to the action of the part of the beam to the right of the section on the part to the left, *viz.*, a left-handed couple the moment of which is $P\,\frac{a\,(l-a)}{l}$, and a downward acting force, $P\,\frac{l-a}{l}$, Fig. 40.

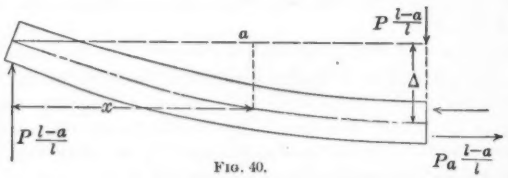

FIG. 40.

This latter force, with the left reaction, forms a couple of moment equal to that at the cut section; hence the system is one in equilibrium, and the exterior work equals the internal work, or

$$P\,\frac{l-a}{l}\,\Delta + \left(P\,a\,\frac{l-a}{l}\right)\alpha = \int_0^a \frac{M^2}{E\,I}\,dx.$$

Substituting the value of Δ, derived previously, writing

$$M = P\,\frac{l-a}{l}\,x$$

and, after effecting the integration, dividing through by $P\,a\,\frac{l-a}{l}$ and solving for α, there is obtained

$$\alpha = \frac{P\,a\,(l-a)\,(2\,a-l)}{3\,E\,I\,l}$$

exactly as given by the author.

Since $2a < l$, α is negative; hence the vertical section under the load rotates α radians in an opposite direction to that of the couple there, or to the right. Mr. Caln.

This, of course, is not the shortest solution of this problem, but it is given to illustrate principles and incidentally to show that the ordinary formulas for beams with immovable abutments do not apply to the segment of the beams, with its loads and reactions, as given in Fig. 40. They do apply, however, to one-half of the beam, when the load is at the center, to find the rotation of a vertical section at the abutment; for the half-beam is in the condition of a cantilever fixed at one end, with a horizontal tangent to the elastic curve, and loaded with $\frac{P}{2}$ at the abutment, acting upward, so that the solution, as in the case of the author's Case I, is quickly effected.

The writer, in conclusion, desires to express his great pleasure in reading the author's stimulating paper, which presents the subject so concisely and, at the same time, so clearly.

GEORGE F. SWAIN,* PAST-PRESIDENT, AM. SOC. C. E. (by letter).— Discussion on this paper would naturally be directed to (1) criticism or commendation of the principle or the writer's presentation of it; or (2), whether, as the writer supposed when he presented it, it was novel. Mr. Swain.

There has been little criticism, except in two instances, of the principle itself, or of its presentation, and the writer here expresses his thanks for the commendatory remarks which have been made by many who have discussed it. As to the principle itself, it is simple and fundamental, and stands alongside the principle of deflection first given by Maxwell, and first published in this country by the writer, as a wholly similar method of finding rotation. There is no question as to its correctness, though one contributor does not admit it.

It should be stated at once that the writer did not claim anywhere that the problems which could be solved by the aid of the principle could not be solved otherwise, in some cases as easily as by its aid, and in some cases more easily than by it. The object was merely to present it as a fundamental principle in the theory of structures which he believed had escaped recognition by American engineers even if, as he suggested, it had been published before, although he was not aware and still does not believe that it had, in its general form. The discussion affords good evidence that it had not been recognized or appreciated, even if it had been known.

Since the paper was published, the writer has found—partly from the references quoted in the discussions, and partly in other ways—that, as he had surmised, the principle had been known in Europe, but only as applied to beams, and not as applied to trusses or combinations.

* Cambridge, Mass.

Mr. Swain.

He does not believe, however, that the principle had been at all recognized or used in America, either for beams or trusses, although it is referred to in one American book, but not explained or illustrated even there. The book referred to is "Bridge Engineering", Vol. I, by J. A. L. Waddell, M. Am. Soc. C. E., where, on page 231, after referring to the formula for the deflection of a beam,

$$\delta = \int_0^l \frac{M\, m\, d\, x}{E\, I},$$

it is stated:

"If it should be desired to find the amount of rotation of a given point of a beam, a couple with a moment of unity can be placed at the said point, and Equation (5) applied by changing δ to α (the angle in radians through which the point turns), the values of m being those produced by the unit couple".

The writer has not found in this book, or any other, any reference to its application to trusses.

Bearing in mind that the writer's paper showed a method of finding the angular rotation of the axis of a piece at any point, due to given loads, whether the piece is a straight or curved beam, or a truss member, or both, it may be well to consider some of the references given by those who claim that the principle is not new.

Professor Parcel states that the principle is not new, but he says it is little understood. He gives several references. The writer does not find in Molitor's work, on page 18 or pages 28-29, or elsewhere, any statement of the principle. Hartmann, pages 9-11, finds rotation only for solid beams, and on pages 24-33 there are only illustrations for solid beams, with no hint of its being a general principle. Mehrtens, at the pages cited, or elsewhere, gives no statement of the principle at all, but treats an entirely different problem, namely, that of finding the angular rotation of a line passing through any two joints of a frame. If a line, L, is drawn through any two joints of a frame, the distance apart of which is m, and if it be desired to find the angular rotation of this line under given loads, this may easily be done by the use of deflections. If a unit load is applied at one of the joints, perpendicular to L, and if this load causes stresses, t, in the members, the deflection of the point in the direction of the unit load due to the actual (not unit) loads will be, by the deflection formula,

$$\sum \frac{t\, s\, l}{E\, A}.$$

If a unit load is applied at the other joint perpendicular to L, but in the other sense, causing stresses, t', the deflection of this point under the actual loads will be

$$\sum \frac{t'\, s\, l}{E\, A}.$$

Mr. Swain.

The sum of these two quantities divided by m, will be the angular rotation of the line; but this will be the same as

$$\sum \frac{t'' s l}{E A},$$

in which t'' is the stress due to a load $\frac{1}{m}$ at each joint, or a unit couple, with one force at each joint. This is easy, and follows, from the deflection formula, but it is not the writer's principle at all.

If Professor Parcel thinks Mehrtens has given the writer's principle, he has failed to grasp that principle. Müller-Breslau is referred to by Professor Parcel. The writer has only the 1907 edition of his "Graphische Statik", but in it finds no statement of his principle. On pages 14-17 the rotation of a line through any two joints, just referred to, is what is found; and on pages 52-57 are historical notes, containing no statement of the principle. Müller-Breslau is also referred to by Professor Church, who cites Equation (54*a*) on page 133. This equation, however, refers only to solid beams, straight or curved, and is in a paragraph of Abschnitt II, which bears the title "Biegungsfestigkeit gerader und einfach gekrümmter Stäbe". His Equation (54*a*) is obtained from Equations (37) and (38), which, as the figures show, apply to solid beams, not trusses. Also, his Equation (54*a*) is

$$t_m = \int \frac{N n d x}{E I}, \text{ etc.},$$

which clearly shows that it applies to a beam. The writer's equation contains $\Sigma \int$, which is very different.

The writer has found no evidence that Müller-Breslau, or any other European writer, had perceived the principle, except as applied to beams, or, if they had, that they have stated it. Of course, it is easy to see, now that the writer has pointed it out, that the principle is implicitly contained in the work equation, but many things are hidden until they are made clear.

Professor Turneaure states that the principle is not new to him. This is not surprising, since it is so simple and obvious; but if Professor Turneaure had perceived it, he evidently did not think it important enough to mention, and the writer cannot in the least agree with his statement that it is "quite fully set forth" in his book. Indeed, the writer does not believe that anybody, reading the paragraph in Professor Turneaure's excellent book to which reference is made, would get even an inkling of the principle. Let any reader test this. In the first place, the paragraph he quotes deals with stresses in redundant members, and in this case the question of angular rotation is not involved. The quoted paragraph refers to structures which include

Mr. Swain.

"members acting as beams". This must mean cases in which the members are acted upon by transverse loads. It cannot refer to secondary stresses, for these are treated in a later chapter which begins with the statement, "It has been assumed heretofore * * * that all members of a truss are free to turn at the joints." What, then, is the meaning of Professor Turneaure's reference to "a bending moment of unity in the redundant member"? At what point in the redundant member? Presumably at the point where the rotation is to be determined. Professor Turneaure, however, nowhere gives any formula for finding rotation analogous to that for finding deflection. The writer's principle deals with a moment unity at the point where the rotation is to be determined, and shows how to find that rotation, and Professor Turneaure nowhere does this. The writer is free to confess that he does not clearly understand Professor Turneaure's quoted paragraph, but he is sure that it does not contain, or even suggest, his principle. Again, the writer has not found anywhere in Professor Turneaure's volumes any statement or illustration of the principle, even for beams.

Replying to Mr. Godfrey, the writer's object was to present a scientific principle and to illustrate its application. Mr. Godfrey thinks that "not one engineer in fifty doing practical designing could follow this paper". That, if true, does not speak very well for engineers, and would suffice to explain the low estimation in which many are held. He also thinks "there is no reason on earth why it [the method] should be applied in a practical design." Well, there was a time, not so long ago, when few engineers "doing practical designing" thought that pins in a bridge should be computed at all, or that the eccentricity of connections was of any importance, and similarly for many other things.

Mr. Godfrey must certainly have perceived that where members or frames are rigidly connected, it is necessary to compute or find an expression for the angular rotation at the points of connection. Sometimes a truss is connected to a beam, sometimes pieces in flexure are connected to other pieces in flexure; and if the engineer is to be something more than a "rule-of-thumb" man, able to solve new problems intelligently, he should have at command the scientific principles which will lead to a solution. The principle given by the writer will be found useful by any structural engineer who has the perception and ability to use it, and those who have not will continue to use "rule-of-thumb" methods, and will either make their structures too light, or waste their clients' money. The principle explained has simplicity for its chief merit, being as easily applied as the usual deflection formula, which few engineers "doing practical designing" knew anything about thirty years ago.

The writer quite agrees with Mr. Godfrey as to the desirability of simplifying construction and also mathematical processes, and thinks

he has done the latter in his paper, as witness his demonstration of the Theorem of Three Moments. It seems, therefore, rather ridiculous to find Mr. Godfrey implying that the writer's paper tended to complicate mathematical processes. The writer also entirely agrees with Mr. Godfrey as to the necessity of common sense in engineering, and the importance of discriminating between important and trivial theoretical matters. He has preached and practiced this doctrine for more than thirty years; but common sense is not guesswork, and one cannot distinguish between important and trivial theoretical matters unless he understands theory. Certainly a man who could not follow through this paper could not so discriminate, and if engineers "doing practical designing" would give more study to simple fundamental principles, of which the paper illustrates one, there would be fewer of the "flimsy and wobbly buildings" that Mr. Godfrey refers to. There are undoubtedly many crimes committed in the name of theory, yet probably not so many as in the name of common sense. The important things are balance, perception, experience, judgment, and a knowledge of fundamental principles. Mr. Swain.

Professor Church's discussion, like everything he writes, is illuminating, and the writer thanks him for his contribution. The difference between the writer's Equation (4) and Müller-Breslau's Equation (54*a*) has been already alluded to. Professor Church's Equation (33) is not quite a correct reproduction of the latter, for reasons already explained.

Two of the discussions, those of Professor Burr and Mr. Janni, criticize the principle itself, as to its correctness or value. Professor Burr has evidently not grasped the principle, and his discussion shows a number of misapprehensions. The principle is not restricted, as he thinks, to "that class of structures in which the axes of members are subject to angular displacement due to stresses of flexure or bending", but it applies to any structure, whether there is flexure or not, as illustrated in Case IV. Professor Burr, however, restricts his discussion to cases of flexure. His statement that the unit moment must be applied to each section is not correct, as is clearly shown by Case II. The unit moment is only applied at the point where the rotation is desired. If the case is that of a beam fixed at one end and free at the other, and the rotation of the free end is desired, the unit moment applied there would cause a unit moment at every section, but this is not true for a beam supported at both ends or for a bar in a frame. Professor Burr's Equation (2), which he appears to think the correct form of the writer's Equation (4), by making $M_r = 1$, is in reality a totally different thing, for it gives the change of slope between two given points, while the writer's Equation (4) gives, as is clearly stated, the angular rotation at a given point. In a beam fixed at one end, his Equation (2) does, of course, give the angular rotation at the free end,

Mr. Swain.

but this is only because there is no rotation at the fixed end. His Equation (2), then, which he states gives the angular displacement of a point in the axis of a beam, only does so when the integration is extended from this point to some other point where the slope is not changed, and this point must first be found, unless its position is obvious, which is not generally the case.

The writer has made no analytical error, as Professor Burr claims. In his first illustration of what he considers this error, Professor Burr has perhaps been misled by the obvious typographical error in the writer's Equation (7), which should not have confused any one. In his second illustration of this error, Professor Burr finds his Equation (8), which is the same as the writer's Equation (4), for the case of a single beam in bending, and in which $d\alpha$ is, of course, the angular rotation only at the point where the unit moment is applied, and he then incorrectly uses this value as if it were the angular rotation at any point.

The writer's Equation (14), alluded to by Professor Burr, is of course the most general form of the Theorem of Three Moments only when the moment of inertia is constant. This is obvious, but perhaps it should have been stated in order that no one might have been misled.

To sum up, Professor Burr has evidently entirely failed to grasp the meaning or application of the principle. The fact, however, that he, who for so long has been an honored and leading member of the Profession, and at the head of one of our best engineering schools, was not only not familiar with the principle, but does not grasp it and denies its correctness when presented, should be sufficient to prove that the paper was needed, and quite a sufficient commentary on the remarks of Mr. Janni, whose discussion will now be considered.

Mr. Janni goes out of his way to find as much fault as he can with the principle and its presentation. Apparently, however, he has not succeeded in finding any ground for denying its correctness. He says it is "obsolete", not having yet perceived that a scientific principle, if correct, can never be obsolete. He says that "any good textbook will give some method of deriving this formula", but he wisely refrains from naming any book which does. He thinks that "any student in any engineering school should know" the principle, and that it is "inferior to modern methods". He then proceeds to attempt to show how much better he could solve structural problems, and begins by stating a mysterious "mathematical truth" which gives the angular rotation of the free end of an elastic body fixed at the other end, using what is called "elastic weight" and "elastic center", terms introduced by Professor Ritter, of Zurich, thirty-two years ago, which, according to Mr. Janni's ideas, should be "obsolete" by this time. He refrains from demonstrating his mathematical truth, but does not state whether this is because "any student in any engineering school" should know it,

or because it is too advanced and modern. If he had approached the discussion in a scientific or even courteous spirit, instead of simply trying to find fault, he might have perceived and pointed out that his "mathematical truth" is most easily demonstrated by the writer's principle, of which that truth is merely a corollary or application; but if the principle is obsolete, perhaps the corollary is also. Referring to his Fig. 33, and using the writer's principle, if a unit moment is applied at the free end the moment at any section is unity, and if y is the distance from the force P (applied at the free end) to any point of the axis of the piece, the moment at that section due to P is Py. Hence, by Equation (4) of the writer's paper Mr. Swain.

$$\alpha = \int_0^l \frac{P y \, d\,l}{E\,I} = P \int_0^l \frac{y \, d\,l}{E\,I},$$

or P times the distance from P to the center of gravity of all the $\frac{d\,l}{I\,E}$'s times the sum of all the $\frac{d\,l}{E\,I}$'s, or, as he expresses it, $P\,G\,d$. This mysterious truth is, therefore, merely a corollary of the writer's principle of this particular case.

Now, it is always better to keep general principles in mind than corollaries, for the latter may be deduced at once if desired. In this way the memory will be relieved as much as possible, and any particular problem may be attacked in the manner best suited to the case.

It is easy now to take up the cases shown by Mr. Janni, and to show that they are either incorrectly solved by him or may be easily solved by the writer's principle, or other and well-known fundamental principles, without using elastic weight or any other conception, which may only complicate while giving the appearance of erudition. This is not said in derogation of the use of the "elastic weight", for no principle of science, and no corollary of one, ever becomes obsolete, but may at times be of use. The point is to emphasize the fundamentals.

Considering Mr. Janni's Case 1: This most elementary case of a beam of constant section fixed at one end is most easily solved by the area moment method, and the slope at the free end may be at once written down from the moment area, or $\frac{P\,l}{2}\,\frac{l}{E\,I}$. The writer's principle is precisely the same, since $M_r = 1$. Elastic weight, therefore, is unnecessary and also confusing here. If the section is not constant, the writer's Equation (7) may be at once written, without the last term, and $\alpha = P$ (sum of each $\frac{d\,x}{E\,I}$ multiplied by its x); while Mr. Janni would have us first find the d of the center of gravity of the

Mr. Swain.

$\frac{dx}{EI}$'s by finding the quantity in parentheses above, and dividing it by the sum of all the $\frac{dx}{EI}$'s, and then multiplying by this same sum. The elastic weight is here neither necessary nor desirable, but merely a complication, as "any student in any engineering school" can easily see. Treating Mr. Janni's second case by the writer's method, a left-handed unit moment applied at D would cause a unit moment at every section of the three parts, and no direct stress. The load, P, produces direct stresses as well as moments, but as the writer explained in his paper, the former are not to be considered. Resolving P at D into horizontal and vertical components, H and V, the moments produced by P are:

In DB, a moment varying from zero at D to Hh at B;
In BA, a moment varying from Hh at B to $(Hh - Vl)$ at A;
In AC, a moment varying from $(Hh - Vl)$ at B (causing compression on the left-hand fibers), to Vl at C (causing compression on the right-hand fibers).

The value of the angular rotation at D may at once be written, observing signs, as

$$EI\alpha = \frac{Hh^2}{2} + Hhl - \frac{Vl^2}{2} + Hh^2 - Vhl - \frac{Hh^2}{2}$$

$$= Hh(l+h) - \frac{Vl}{2}(l+2h).$$

If the load P is under control it may sometimes be of use to recognize that, if it passes through the point G, α will be zero, but this is shown just as simply by the ratio of V to H given by the above equation, as by finding G.

Mr. Janni's Case 3 is the same as that illustrated by Fig. 33 and the writer has already shown that his principle gives the solution more simply and easily than Mr. Janni's method. Referring to his Case 4, if we observe what Mr. Janni's method really is, we shall see that it is inaccurate, and that so far as it is correct it is merely a "camouflaged" application of very old principles. To find the angular rotation of the bar B at the point 13 under a force F at 13, it is clear that the lower chord bars will be in compression and the upper chord bars in tension. Any shortening of the distance 1-3 will cause a rotation about the point 2, and if S is the stress in 1-3, the shortening will be $\frac{Sl}{EA}$ and the angular rotation about 2 will be $\frac{Sl}{EAr}$. For a load F at 13, the value

of S will be $\frac{F a_2}{r}$, if a_2 is the distance from 2 to F, hence the angular rotation will be $\frac{F l a_2}{E A r^2}$, and this rotation will affect all the structure beyond 2. The same is true for each chord bar, all rotations being in this case in the same direction; hence the total angular rotation of B will be $F \Sigma \frac{l a}{E A r^2}$, in which a is the distance of any point from F, and l the length of the chord bar opposite the joint, E and A its modulus of elasticity and area, and r its distance from the joint. If a force, $\frac{l}{E A r^2}$, is considered to act at the joint opposite l, this angular rotation is merely F (sum of moments of these forces about any point in the line of F). This sum may be found by the elementary principle of graphical statics, by drawing the string polygon for these loads, drawing through the point about which the moment is desired a vertical line (that is, prolonging F), and finding the intercept, y, between the end strings. The moment will be the pole distance times y, and by taking the pole distance as $\sum \frac{l}{E A r^2} = G$, then $G y$ is the moment, and this times F is the rotation.

This is not modern, but is merely using Culmann's principle of finding moments graphically. One wonders that Mr. Janni did not consider this principle obsolete. Mr. Janni's application, however, is erroneous, because he neglects all the web members. In solid beams, the deformation due to shear is often or generally neglected because (1) it cannot be accurately determined, and (2) it is often or generally small. In trusses, the deformation due to shear may be determined as accurately as for the chords, and it may be considerable. Professor Ritter cites a case in which the deflection due to web members was 41% of the total. There is no excuse here for neglecting the web. By the writer's principle, the stress in every member would be found; the unit moment being applied at 13, the stress in every chord piece due to it would be $\frac{1}{r}$ and the stress due to F would be $F a \div r$. The web would be similarly included. The summations may be made more quickly, easily, and much more accurately than by Mr. Janni's method, which does not and cannot well include the web, and which is therefore distinctly inferior. This example well illustrates the danger of using methods that one does not thoroughly understand, and the importance of grasping and adhering to fundamental principles.

The writer cordially thanks Messrs. Hudson, Mensch, Eddy, Cain, and Maney for their interesting contributions, which call for no specific comment.

Mr. Swain. To sum up, it is no doubt true, as pointed out by Messrs. Church, Eddy, Cain, and Mensch, that the writer's principle is implicitly contained in Castigliano's work equation. So was the latter implicitly contained in the law of the conservation of energy, and the principles of dynamics in Newton's laws of motion. The writer, however, has not found in Castigliano any statement of this principle of rotation. He admits that the principle as applied to beams was known in Europe, but he has not found it explained in any American book, neither in Church, Molitor, Turneaure, Hudson, nor any other. Further, he still fails to see that any author, anywhere, has clearly shown its general applicability, to trusses as well as to beams, or even stated it, as a principle analogous to the deflection principle of Maxwell. Hence, he still thinks it may be called new.

Paper No. 1439

PRESSURES IN PENSTOCKS CAUSED BY THE GRADUAL CLOSING OF TURBINE GATES

By Norman R. Gibson, M. Am. Soc. C. E.

With Discussion by Messrs. Otto V. Kruse, Eugene E. Halmos, R. D. Johnson, Minton M. Warren, T. Noble Anderson, Ford Kurtz, William P. Creager, and Norman R. Gibson.

Synopsis.

This paper shows how the rise of pressure caused by the gradual closing of turbine gates may be determined from Professor Joukovsky's theory of maximum water-hammer. A solution of the problem by the trial-and-error method of arithmetic integration is first given, and then formulas are derived that cover any governor time and any relation between governor stroke and gate movement. Two factors which affect the rise of pressure are taken into consideration: (1) the elasticity of water and of the walls of the penstock; and (2) the effect of the net head on the phenomena which occur during the closing of the gates. Previous writers have submitted formulas which neglect one or other of these two factors, with the result that they do not give correct results in all cases. The limitations of such formulas are determined by the solution of the problem herein submitted.

Introduction.

The purpose of this paper is to show how the excess pressure in penstocks caused by the gradual closing of turbine gates may be determined from Professor Joukovsky's theory of water-hammer. It will be assumed that the theory of pressure waves, their amplitudes, and speeds of propagation, as formulated by him and proved by his experiments, may be accepted as correct.

At the risk of wearying the reader who is familiar with Joukovsky's work, it is necessary, in connection with what is to follow, to summarize as briefly as possible the principles demonstrated a number of years ago by this distinguished Russian. For a partial translation of his work, the reader is referred to Miss O. Simin's paper entitled "Water Hammer"* which should be examined carefully by every student of this subject.

Joukovsky's experiments, made in 1898 at Moscow, were confined to the instantaneous stopping of the flow of water in long pipes. By his experiments he was able to prove the soundness of his analytical determination of the maximum rise of pressure that would occur when the flow of water in a pipe was suddenly arrested. The casual thinker at first would imagine that—as force is equal to the product of mass by acceleration—an infinite pressure would be produced in a pipe if the water flowing in it were stopped instantaneously. On second thought, he would realize that neither the water column nor the walls of the pipe are rigid, and, therefore, the pressure caused by the shock of stopping the flow suddenly is relieved by the slight compression of the water and the expansion of the walls of the pipe. It was the effect of these two factors that was determined by Professor Joukovsky. He showed that the shock pressure is transmitted along the column of water in the pipe in waves similar to sound waves; and that the shock pressure is proportional to the destroyed velocity of flow and to the speed of propagation of the pressure waves. This speed depends on the compressibility of water, on the elasticity of the materials of the pipe, and on the ratio of the thickness of the walls of the pipe to its diameter. In other words, if the speed of the pressure wave is known, the maximum pressure produced (called water-hammer) by instantane-

* *Proceedings*, Am. Water Works Assoc., 1904, p. 341.

ously stopping water flowing in a pipe at any velocity may be calculated.

Joukovsky's formula for water-hammer is:

$$h = \frac{a\,V}{g} \qquad (1)$$

where h = excess pressure, in feet;

V = velocity of flow in the pipe, in feet per second;

g = gravitational unit, in feet per second per second;

and a = velocity of the pressure wave, in feet per second, which is determined by the formula:

$$a = \frac{12}{\sqrt{\frac{W}{g}\left(\frac{1}{k} + \frac{d}{E\,e}\right)}} \qquad (2)$$

where W = weight of a cubic foot of water, in pounds;

g = gravitational unit, in feet per second per second;

k = voluminal modulus of water, in pounds per square inch;

d = diameter of pipe, in inches;

e = thickness of pipe walls, in inches;

E = modulus of elasticity of material of pipe walls, in pounds per square inch.

Joukovsky showed also that the shock pressure is transmitted along the pipe with constant intensity and "at constant velocity, which seems to be independent of the intensity of the shock."

"The speed of propagation of the pressure wave remains the same, whether the shock is caused by arresting the flow of a column of water moving in a pipe, or by suddenly changing the pressure in the column of water (flowing or standing) in any part and by any other means."

"If the water column continues flowing, such flow exerts no noticeable influence upon the shock pressure. In a pipe from which water is flowing, the pressure wave is reflected from the open end of the pipe, in the same way as from a reservoir with constant pressure."

"The phenomenon of periodical vibration of the shock pressure is completely explained by the reflection of the pressure wave from the ends of the pipe, *i. e.*, from the gate and from the origin [of the pipe]."*

Pressure waves, after traveling up the penstock to the origin or point of relief and back to the gate, are reflected and transmitted again

* Quotations are from "Water Hammer," by Miss O. Simin.

over the same course, as waves of rarefaction or sub-normal pressure. In this manner pressure waves, alternately super-normal and sub-normal, travel up and down the penstock until damped out by friction. During the time taken by the wave to traverse its course from gate to origin the pressure at the gate remains at its full value, either super-normal or sub-normal, as the case may be.

Briefly stated, then, the premises are: that when water flowing in a pipe is suddenly arrested, certain pressure waves, the characteristics of which are known, are produced and propagated along the pipe at constant speed and constant magnitude, and that the speed and magnitude of these waves may be calculated for any given conditions.

Fundamental Equations.

It is the writer's intention to apply herein this theory of pressure waves to the phenomena which occur when the gates of a turbine at the end of a penstock are gradually closed. The damping effect of friction on the pressure waves will be neglected during the time of closure. The variable velocity of the pressure wave due to the difference in density of the water at the top and bottom of the penstock will also be neglected. For the sake of simplicity, it will be assumed that the gate opening is closed uniformly from full open to shut by a governor which moves the gates at uniform velocity from the beginning of its stroke to the end, and that the area of gate opening is directly proportional to the amount of gate movement. It may be stated here, parenthetically, that the resulting formulas may be modified, easily, to suit any method of gate closure, whether the speed of closing and the relation of governor movement to area of gate opening is uniform or variable.

When the gates of a turbine are closed gradually the velocity of the water in the penstock is reduced to zero and the pressure in the penstock rises. It is frequently assumed that the reduction in velocity takes place uniformly, but the rise of pressure, which commences immediately after the gates begin to move, increases the velocity of discharge through the gate opening, and, during the early part of the gate movement, tends to diminish the rate at which the flow of the water is retarded. This variable rate of retardation, during the time the gates are being closed, has an important bearing on the resulting rise of pressure, and it is necessary to take it into consideration by

determining the relation between the velocity of flow and the pressure in the penstock. This relation may be expressed by the equation:

$$V_0 = B_0 \sqrt{H_0} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

where V_0 = initial velocity, in feet per second, of the water in the penstock before shut down;

H_0 = normal net head, in feet;

and B_0 = a number representing the gate opening. The value of B_0 is best determined from the known value of V_0 and H_0, but, in fact, B_0 is the ratio of the area of the gate opening to the area of the penstock multiplied by $\sqrt{2g}$ times the coefficient of discharge of the gate opening.

At any time during the closing of the gates the relation between V, B, and H would be expressed by the general formula, $V = B\sqrt{H}$. If the gates are closed in the time, T, and t is the time from the beginning of the stroke to any time before the end of the stroke, the value of B_t (that is, B at the end of the time, t) for uniform closing, would be $\left(1 - \frac{t}{T}\right) B_0$. During the time, t, the pressure in the penstock has risen an amount, h_t, so that the net head, H_t (that is, H at the end of the time, t) would be equal to $H_0 + h_t$. Therefore, the expression for the value of V_t (that is V at the end of the time, t) is:

$$V_t = \left(1 - \frac{t}{T}\right) B_0 \sqrt{H_0 + h_t} \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Calculation by Arithmetic Integration.

Before proceeding with the analytical determination of h_t, it will perhaps make the work clearer to show first, by a numerical example, how h_t may be otained by the trial-and-error method of arithmetic integration. Assume that the gate, instead of being moved in a continuous uniform manner, is closed by a series of small instantaneous movements with a slight pause between each movement. Each little movement of the gate would destroy instantaneously a small part, ΔV, of the velocity, V_0, and, since this part of the velocity is destroyed instantaneously, the rise of pressure, according to Joukovsky, would be $h = \frac{a \Delta V}{g}$. When the first instantaneous movement has taken place, let

a pause of time, t, elapse before the next movement. Then $\Delta V = V_0 - V_t$, and $h_t = \frac{a\,(V_0 - V_t)}{g}$.

By these equations and Equation (4) a numerical example may now be solved, and at the same time there will be explained other interesting phenomena caused by the closing of the gates and the pressure waves produced thereby. The analytical work may then be more readily understood.

Let $L = 820$ ft.;

$V_0 = 11.75$ ft. per sec.;

$H_0 = 165$ ft.;

$T = 2.1$ sec. (For convenience, T has been chosen an even multiple of $\frac{2L}{a}$);

$a = 4\,680$ ft. per sec. (This value of a is chosen simply because this example was worked out by the writer for a pipe in a tunnel and concreted in. The expansion of the pipe walls, therefore, was neglected. For any condition, a may be obtained by Equation (2)).

Since $V_0 = B_0 \sqrt{H_0}$, then $B_0 = 0.91476$.

Assume that the gates are closed in 24 successive instantaneous movements. The time elapsing between each movement would then be 0.0875 sec. After the first of these movements had taken place the gates would have been closed one-twenty-fourth of their opening, and the number representing the gate opening would have been reduced by one-twenty-fourth of its value, that is, $\frac{0.91476}{24} = 0.038115$. At each of the successive movements the value of B is reduced by the same amount, as the gate motion is assumed to be uniform. It will not be necessary, however, to use more than the first three significant figures, and the work may be done on the slide-rule. In this example the recovery of the friction head in the penstock will be neglected.

From the foregoing may now be written the first three columns of Table 1, and the first line of Columns 4 and 5. The table may then be completed as follows: Assume a trial reduction in velocity, caused by the initial instantaneous movement of the gate, and set the figure down in Column 5 under the value of V_0 and subtract it from V_0, placing

TABLE 1.—By Arithmetic Integration.

Data: $L = 820$ ft. $V_0 = 11.75$ ft. per sec. $H_0 = 165$ ft. $T = 2.1$ sec. $a = 4\,680$ ft. per sec. Friction neglected.

the difference immediately underneath. This trial figure is ΔV, and is assumed to be destroyed instantaneously by the first movement of the gate. A pressure wave, Δh, of magnitude, $\frac{a\,\Delta v}{g} = \frac{4\,680}{32.2}(\Delta V) = 145\,\Delta V$, is therefore started up the pipe. The product of $145\,\Delta V$ is set down

in Column 6 opposite ΔV. In Column 7 is recorded the algebraic sum of the values of Δh. Having obtained the figure in Column 7, it is added to the net head, $H_0 = 165$, and the sum is set down in the next line lower in Column 4. The result must now be checked, to see that $B\sqrt{H} = V$, where B is 0.8766 and H and V have the values recorded in their respective columns opposite B. If the relation is not satisfied, a new trial value of ΔV must be chosen, and the operations repeated until a check is obtained. After trial, the initial value of ΔV was found to be 0.085. Proceeding in this way, the rise of pressure at the end of 0.35 sec. is found to be 56.80 ft. This rise has taken place in four successive jumps.

At this point it becomes necessary to trace the course of the pressure wave started up the penstock by the initial movement of the gate. This wave has a velocity of 4 680 ft. per sec., and travels at that rate toward the forebay or origin of the penstock; after arriving at the origin it is reflected and returns to the gate at the same velocity. The distance from gate to forebay and return is 1 640 ft., so that the pressure wave takes 0.35 sec. to cover this distance. On its arrival at the gate it is reflected immediately as a wave of sub-normal pressure, and commences its journey again from gate to forebay and back. At the instant the wave becomes sub-normal, however, the gate is given one of its instantaneous closing movements, causing a further reduction in the velocity of the water flowing in the penstock and the consequent rise of pressure incident thereto. Thus, at this instant, two factors have to be taken into consideration: the rise of pressure caused by the fifth little instantaneous movement of the gate and the fall in pressure caused by the change from super-normal to sub-normal of the pressure wave produced by the first or initial movement of the gate which occurred 0.35 sec. before.

By trial-and-error the velocity that has been destroyed by the fifth movement of the gate is found to be 0.258 ft. per sec., and the result is checked as follows. Multiplying 0.258 by 145, the magnitude of the resulting pressure wave is 37.4 ft., and this added to 56.80 would make the total excess pressure existing equal to 94.20 ft., were it not for the fact that the initial wave has returned to the gate and become sub-normal. The amount of the initial wave, as shown by the second line of Table 1, is 12.32, and since it not only falls to zero but passes below zero to a sub-normal pressure of equal amount, there must be subtracted

twice 12.32 from 94.20, making the net excess pressure existing at that instant 69.56 ft. Adding this to the initial net head, $H_0 = 165$, the value of V is checked as before by the formula, $V = B\sqrt{H}$.

Proceeding then as before, and remembering that the pressure rise caused by the sixth movement of the gate is reduced by the fall to sub-normal of the wave produced by the second movement of the gate, and the pressure rise of the seventh movement is reduced by the wave produced by the third movement, and so on, there may be calculated the successive increments of pressure.

For convenience, the time required by the pressure waves to travel from the gate to the origin of the pipe and return to the gate again will be called one interval. The interfering waves referred to in the foregoing paragraph are then always one interval apart.

After the eighth movement of the gate has taken place, it is found that the net excess pressure has reached 114.00 ft. At the instant the ninth movement takes place it must be noted that the pressure wave produced by the first movement of the gate, which has traveled, during the first interval, from the gate to the origin and back as a wave of super-normal pressure, and during the second interval over the same course as a wave of sub-normal pressure, has now returned to the gate and, again becoming super-normal, is again reflected and commences its journey from gate to origin and back. Thus, at the ninth movement of the gate, there must be taken into consideration the pressure wave caused by the instantaneous destruction of the velocity at that instant, the sub-normal wave due to the fifth movement, and the super-normal wave due to the first movement. After adding to the excess pressure existing at the end of the eighth movement, the rise of pressure caused by the ninth movement, there must be subtracted twice the pressure caused by the fifth movement, and there must be added twice the pressure caused by the first movement, or, in other words, there is subtracted twice the difference between the fifth and first waves.

By thus keeping in mind the position of the wave propagated by each movement of the gate, Table 1 may be completed, and the resulting maximum rise of pressure is found to be 217.70 ft.

Fig. 1 is a series of graphical diagrams showing the magnitude of the pressure waves caused by the successive instantaneous movements of the gate. A separate diagram is drawn for each movement, pressure being represented by the ordinates and time by the abscissas

The change from super-normal to sub-normal and *vice versa* is shown at the end of each interval of time. Fig. 2 is the excess pressure-time curve plotted from the figures in Column 7 of Table 1, or, what amounts to the same thing, from the algebraic sum of the pressure waves shown in Fig. 1.

Table 2 shows the method of determining the results when the recovery of friction in the penstock is included, an example being selected where the friction head is an appreciable quantity. The

TABLE 2.—By Arithmetic Integration.

Data: $L = 6\,337$ ft. $V_0 = 15.055$ ft. per sec. $H_0 = 1\,260$ ft. $T = 69.5$ sec. $a = 3\,647$ ft. per sec. Friction head $h_f = 81$ ft.

FIG. 1.

operations are almost identical with those just described, up to Columns 6 and 7. To avoid reference to the foregoing, however, the formation of Table 2 will be described from the beginning. In the first line, opposite B = 0.4241, set down in Columns 3, 4, and 7, the known values of H_0, V_0, and h_f (friction head). Next, assume a trial reduction in velocity, caused by the initial instantaneous movement of the gate, and set the figures down in Column 4 under the value of V_0, and

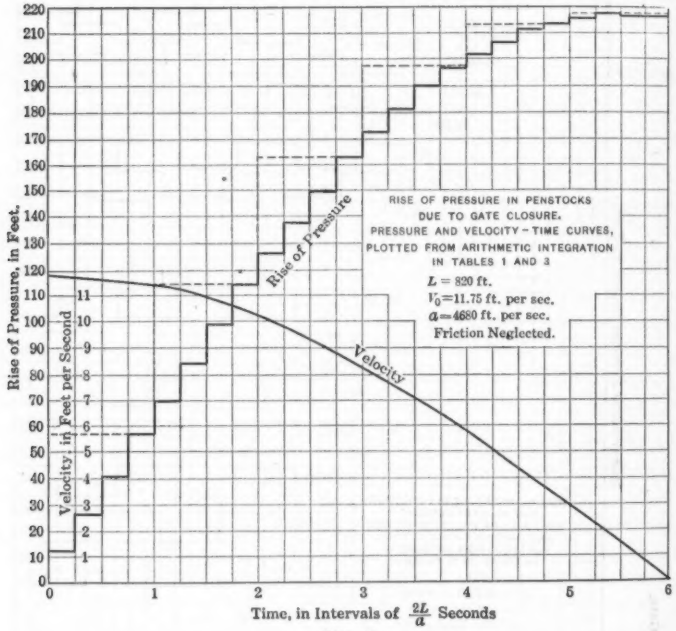

FIG. 2.

subtract it from V_0, placing the difference immediately underneath. This trial figure is ΔV, and is assumed to be destroyed instantaneously by the first movement of the gate. A pressure wave, Δh, of magnitude $= \frac{(\Delta V)\, a}{g} = (\Delta V)\frac{3647}{32.2} = 113\ \Delta V$, therefore, is started up the pipe. The product of 113 ΔV is set down in Column 5 opposite ΔV. In Column 6 is recorded the algebraic sum of the values of Δh. In Column 7 the total friction head, due to the velocity shown in Column 4, is set down, and, in Column 8, the friction head recovered at each

operation is shown. For convenience, h_f may be made equal to $F\ V^2$, in which F is a coefficient obtained from the known values at the beginning. In the example, $F = 0.3574$. Column 9 shows the sum of the opposite items in Columns 6 and 8. Having obtained the figure in Column 9, it is added to the net head, $H_0 = 1\,260$, and the sum is set down in the next lower line in Column 3. The result must now be checked to see that $B \sqrt{H} = V$, where B is now 0.4168, and H and V are the values opposite. If the relation is not satisfied, a new trial value of ΔV must be chosen, and the operations repeated until a check is obtained. After trial, the initial value of ΔV was found to be 0.155. The operations for obtaining the figures on the third line are not quite the same as those just described, because, after assuming the next trial value of ΔV, and multiplying it by 113, it must be remembered that the resulting pressure at the gate is reduced by the return of the first wave, which has traveled up to the forebay and back, and now changes to sub-normal and repeats the journey. The time at which the gate is given its second movement has been selected purposely to coincide with the return of the first wave. The item opposite Interval 2, in Column 6, therefore, is the difference between the first two figures in Column 5. The other operations are similar to those already described, and the resulting figures in Columns 3 and 4 are checked similarly with the value of $B = 0.4084$. The succeeding lines are filled in by the same process, always keeping in mind the return of the preceding waves, and whether they change to sub-normal or super-normal. A little study will disclose the fact that the figure in the second line of Column 6 may be obtained by subtracting the figure in the first line of Column 6 from the figure in the second line of Column 5. Similarly, the figure in the third line of Column 6 may be obtained by subtracting the figure in the second line of Column 6 from the figure in the third line of Column 5, and so on.

At this point it is interesting to repeat the trial-and-error work for the foregoing example worked out in Table 1, but using only 6 instantaneous movements of the gate instead of 24. The results are shown in Table 3, and the pressure-time curve in dotted lines in Fig. 2. From these it will be noted that the total rise of pressure is the same as that obtained by the calculations for 24 movements, and, moreover, the resulting pressure at the end of each interval is the same in both cases. Although six movements of the gate, or one movement to each

interval of time, are sufficient to determine the pressure rise at the end of each interval, it requires the larger number of movements to obtain intermediate points on the pressure-time curve. If a still greater number of movements is taken, the increments in pressure rise become smaller, and, in the limit, the stepped diagrams similar to Fig. 2 would become a series of smooth curves from the beginning to the end of each interval. The diagram, however, would not necessarily form a smooth curve from the beginning to the end of the closing time, because cusps or changes of curvature at the end of each interval result from the action of the pressure waves in changing at that instant from super-normal to sub-normal or *vice-versa*. When the duration of closure is short, the change of curvature in the diagram at the end of each interval is frequently very apparent; but, when the duration of closure is long, the changes of curvature in many cases cannot be detected by the eye. These changes of curvature at the end of the intervals make it difficult to formulate the integration which can be performed so easily by the trial-and-error work already explained.

It is possible, however, to obtain a series of equations, one for each interval of the closing time, that constitute a direct mathematical solution of the problem, without recourse to trial-and-error methods. The foregoing example has been explained in order that the analytical work may be more easily understood, and in order that the method of tracing the course of the pressure waves and keeping track of their periodic changes may be kept clearly in mind. More particularly, it should

be borne in mind that though a formula may be written for the pressure rise in the first interval, using only the known quantities existing before the shut-down, the formulas for the pressure rise in any succeeding interval will involve, as one of the known quantities, the value of the pressure rise at the end of the preceding interval. It thus becomes necessary, when calculating the pressure rise at any time during, or at the end of, the closing of the gate, to obtain first the amount of the pressure rise at the end of each preceding interval. Moreover, if it is desired to determine the pressure rise at any time between the beginning and end of any interval—that is, at any fractional part of an interval—not only is it necessary to determine the pressure rise at the end of each preceding interval, but also the pressure rise at the same fractional part of each preceding interval. This also applies in determining the excess pressure-time curve when the duration of closure is not exactly a whole number of intervals.

NOMENCLATURE.

L = length of penstock, in feet;

a = velocity of pressure wave, in feet per second;

g = acceleration due to gravity, in feet per second per second;

$\frac{2L}{a}$ = one interval of time;

T = governor time, in seconds, *i. e.*, total duration of gate closure;

$T_1, T_2, T_3, \ldots T_n$ = time at the end of the 1st, 2d, 3d, ... nth interval;

$t_1, t_2, t_3, \ldots t_n$ = any time during the 1st, 2d, 3d, ... nth interval;

n = any number of intervals; the final interval in the time, T, need not be complete;

H_0 = normal net head, in feet;

$h_1, h_2, h_3, \ldots h_n$ = excess pressure above normal, in feet, existing at the end of the 1st, 2d, 3d, ... nth interval, *i. e.*, at the times, $T_1, T_2, T_3, \ldots T_n$;

$h_{t_1}, h_{t_2}, h_{t_3}, \ldots h_{t_n}$ = excess pressure above normal, in feet, at any time during the 1st, 2d, 3d, ...nth interval, *i. e.*, at the times, $t_1, t_2, t_3, \ldots t_n$;

V_0 = initial velocity, in feet per second, of the water in the penstock before shut-down.

$V_1, V_2, V_3, \ldots V_n$ = velocity, in feet per second, of the water in the penstock at the end of the 1st, 2d, 3d, ... nth interval;

$V_{t_1}, V_{t_2}, V_{t_3}, \ldots V_{t_n}$ = velocity, in feet per second, of the water in the penstock at any time, $t_1, t_2, t_3, \ldots t_n$, during the 1st, 2d, 3d, ... nth interval;

$B_0 = \sqrt{\frac{V_0}{H_0}}$ = a number representing the gate opening;

$$S_{t_1} = \left(\frac{a}{g}\right)^2 \left(1 - \frac{t_1}{T}\right)^2 B_0^2 \qquad R_0 = \frac{a}{g} V_0$$

$$S_{t_2} = \left(\frac{a}{g}\right)^2 \left(1 - \frac{t_2}{T}\right)^2 B_0^2 \qquad R_{t_1} = h_1 + \frac{a}{g} V_1 - C_{t_1}$$

$$S_{t_n} = \left(\frac{a}{g}\right)^2 \left(1 - \frac{t_n}{T}\right)^2 B_0^2 \qquad R_{t_2} = h_2 + \frac{a}{g} V_2 - C_{t_2}$$

$$C_{t_1} = 2\frac{a}{g}(V_0 - V_{t_1}) \qquad R_{t_{n-1}} = h_{n-1} + \frac{a}{g} V_{n-1} - C_{t_{n-1}}$$

$$C_{t_2} = 2\frac{a}{g}(V_1 - V_{t_2}) - C_{t_1} \qquad Z_1 = \frac{\left(\frac{a}{g}\right)^2 S_{t_1}}{\left(\frac{a}{g}\right)^2 + S_{t_1} F}$$

$$C_{t_n} = 2\frac{a}{g}(V_{n-1} - V_{t_n}) - C_{t_{n-1}}$$

F = a friction factor such that $F V^2$ = total loss, in feet of head, for velocity, V;

$$Z_2 = \frac{\left(\frac{a}{g}\right)^2 S_{t_2}}{\left(\frac{a}{g}\right)^2 + S_{t_2} F}$$

$$Z_n = \frac{\left(\frac{a}{g}\right)^2 S_{t_n}}{\left(\frac{a}{g}\right)^2 + S_{t_n} F}$$

Time is always to be measured from the beginning of the gate movement. Thus, the time, t_2, is the time from the beginning of the stroke to some time between the first and third intervals. The successive values of t_1, t_2, etc., must always be one interval apart.

First: Derivation of Formulas with Friction Neglected.—Joukovsky's formula for water-hammer, as already stated in Equation (1), is:

$$h = \frac{a V}{g}$$

During slow closing of the gate, $d\,h = \frac{a}{g}\,d\,V$.

At the beginning of the closing time, as already stated in Equation (3),

$$V_0 = B_0\,\sqrt{H_0}$$

and, in general, $$V = B\,\sqrt{H_0 + h}.$$

For the first interval:

$$\int_0^{h_{t_1}} d\,h = \frac{a}{g}\int_{V_{t_1}}^{V_0} d\,V$$

where h_{t_1} = pressure rise at any time, t_1, during the first interval, and V_{t_1} = velocity at the time, t_1, during the first interval.

Integrating, then:

$$h_{t_1} = \frac{a}{g}\,(V_0 - V_{t_1}) \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

Since V_{t_1} must be proportional to the gate opening multiplied by the square root of the head, then, for uniform gate motion:

$$V_{t_1} = \left(1 - \frac{t_1}{T}\right) B_0\,\sqrt{H_0 + h_{t_1}} \ldots\ldots\ldots\ldots\ldots (6)$$

Substituting this value of V_{t_1} in the equation for h_{t_1}, the latter becomes:

$$h_{t_1} = \frac{a}{g}\,V_0 - \frac{a}{g}\left(1 - \frac{t_1}{T}\right) B_0\,\sqrt{H_0 + h_{t_1}}$$

For simplicity, substitute the symbol, R_0, in place of $\frac{a}{g}\,V_0$, and the symbol, $\sqrt{S_{t_1}}$, for $\frac{a}{g}\left(1 - \frac{t_1}{T}\right) B_0$.

Thus: $h_{t_1} = R_0 - \sqrt{S_{t_1}\,(H_0 + h_{t_1})}$

Squaring: $(h_{t_1} - R_0)^2 = S_{t_1}\,(H_0 + h_{t_1})$

Expanding: $h_{t_1}^{\,2} - 2\,h_{t_1}\,R_0 + R_0^{\,2} = S_{t_1}\,H_0 + S_{t_1}\,h_t$

Collecting: $h_{t_1}^{\,2} - h_{t_1}\,(S_{t_1} + 2\,R_0) + R_0^{\,2} - S_{t_1}\,H_0 = 0$

Solving: $$h_{t_1} = \frac{1}{2}\left\{(S_{t_1} + 2\,R_0) \pm \sqrt{(S_{t_1} + 2\,R_0)^2 - 4\,R_0^{\,2} + 4\,S_{t_1}\,H_0}\right\}$$

Simplifying: $$h_{t_1} = \frac{1}{2}\left\{(S_{t_1} + 2\,R_0) \pm \sqrt{S_{t_1}\,(S_{t_1} + 4\,R_0 + 4\,H_0)}\right\} \ldots\ldots (7)$$

For the second interval, an examination of Table 1 will show that

$$\int_0^{h_{t_2}} d\,h = \frac{a}{g}\int_{V_{t_2}}^{V_1} d\,V + h_1 - 2\,\frac{a}{g}\int_{V_{t_1}}^{V_0} d\,V$$

Where h_{t_2} = pressure rise at any time, t_2, during the second interval;
V_{t_2} = velocity at the time, t_2;
V_1 = velocity at the end of the first interval;
h_1 = pressure rise at the end of the first interval;
V_{t_1} = velocity at the time, t_1, which must be exactly one interval before the time, t_2.

Integrating: then $h_{t_2} = \frac{a}{g}(V_1 - V_{t_2}) + h_1 - 2\frac{a}{g}(V_0 - V_{t_1})$....(8)

Substituting C_{t_1} for $2\frac{a}{g}(V_0 - V_{t_1})$

$$h_{t_2} = \frac{a}{g}(V_1 - V_{t_2}) + h_1 - C_{t_1}$$

Again, since V_{t_2} must be proportional to the gate opening multiplied by the square root of the head, then, for uniform gate motion:

$$V_{t_2} = \left(1 - \frac{t_2}{T}\right) B_0 \sqrt{H_0 + h_{t_2}} \quad \text{.....(9)}$$

Substituting this value of V_{t_2} in the equation for h_{t_2} the latter becomes

$$h_{t_2} = \frac{a}{g} V_1 - \frac{a}{g}\left(1 - \frac{t_2}{T}\right) B_0 \sqrt{H_0 + h_{t_2}} + h_1 - C_{t_1}.$$

Substituting the symbol, R_{t_1}, in place of $\frac{a}{g} V_1 + h_1 - C_{t_1}$, and the symbol, $\sqrt{S_{t_2}}$, for $\frac{a}{g}\left(1 - \frac{t_2}{T}\right) B_0$,

$$h_{t_2} = R_{t_1} - \sqrt{S_{t_2}(H_0 + h_{t_2})}$$

Squaring: $(h_{t_2} - R_{t_1})^2 = S_{t_2}(H_0 + h_{t_2})$

Expanding: $h_{t_2}^2 - 2 h_{t_2} R_{t_1} + R_{t_1}^2 = S_{t_2} H_0 + S_{t_2} h_{t_2}$

Collecting: $h_{t_2}^2 - h_{t_2}(S_{t_2} + 2 R_{t_1}) + R_{t_1}^2 - S_{t_2} H_0 = 0$

Solving: $h_{t_2} = \frac{1}{2}\left\{(S_{t_2} + 2 R_{t_1}) \pm \sqrt{(S_{t_2} + 2 R_{t_1})^2 - 4 R_{t_1}^2 + 4 S_{t_2} H_0}\right\}$

Simplifying: $h_{t_2} = \frac{1}{2}\left\{(S_{t_2} + 2 R_{t_1}) \pm \sqrt{S_{t_2}(S_{t_2} + 4 R_{t_1} + 4 H_0)}\right\}$..(10)

In a similar manner, the value of h, at any time in any interval, may be found.

Second: Derivation of Formulas with Friction Included.—In the foregoing analysis no account has been taken of the effect of frictional losses of head in the penstock. As the velocity in the penstock is gradually destroyed, the friction head is gradually recovered and is

added to the net head, producing discharge through the turbine gates. In any penstock the total frictional losses may be assumed to be proportional to the square of the velocity of flow, and may be represented by a coefficient, F, such that $FV^2 =$ total loss in feet of head for a velocity, V. The velocity head recovered at any time in the first interval, therefore, is $F\,V_0^2 - F\,V_{t_1}^2$. This head must then be added to the sum of $H_0 + h_{t_1}$, in determining the relation between velocity, gate opening, and head, as given by Equation (6).

Thus: $$V_{t_1} = \left(1 - \frac{t_1}{T}\right) B_0 \sqrt{H_0 + h_{t_1} + F\,V_0^2 - F\,V_{t_1}^2}$$

Squaring: $$V_t^2 = \left(1 - \frac{t_1}{T}\right)^2 B_0^2 \,(H_0 + h_{t_1} + F\,V_0^2 - F\,V_{t_1}^2)$$

Collecting: $$V_{t_1}^2 \left\{1 + \left(1 - \frac{t_1}{T}\right)^2 B_0^2\, F\right\} = \left(1 - \frac{t_1}{T}\right)^2 B_0^2 \,(H_0 + h_{t_1} + F\,V_0^2)$$

Solving, and multiplying numerator and denominator by $\frac{a}{g}$:

$$V_{t_1} = \sqrt{\frac{\left(\frac{a}{g}\right)^2 \left(1 - \frac{t_1}{T}\right)^2 B_0^2 \,(H_0 + h_{t_1} + F\,V_0^2)}{\left(\frac{a}{g}\right)^2 + \left(\frac{a}{g}\right)^2 \left(1 - \frac{t_1}{T}\right)^2 B_0^2\, F}}$$

Substituting S_{t_1} for $\left(\frac{a}{g}\right)^2 \left(1 - \frac{t_1}{T}\right)^2 B_0^2$,

$$V_{t_1} = \sqrt{\frac{S_{t_1}\,(H_0 + h_{t_1} + F\,V_0^2)}{\left(\frac{a}{g}\right)^2 + S_{t_1} F}} \qquad \text{.....(11)}$$

Inserting this value of V_{t_1} in Equation (5) for h_{t_1},

Then: $$h_{t_1} = \frac{a}{g} V_0 - \frac{a}{g} \sqrt{\frac{S_{t_1}\,(H_0 + h_{t_1} + F\,V_0^2)}{\left(\frac{a}{g}\right)^2 + S_{t_1} F}}$$

Solving for h_{t_1} in the same manner as that used in obtaining Equation (7), and substituting R_0 in place of $\frac{a}{g} V_0$, and Z_1 in place of

$$\frac{\left(\frac{a}{g}\right)^2 S_{t_1}}{\left(\frac{a}{g}\right)^2 + S_{t_1} F},$$

Then: $$h_{t_1} = \frac{1}{2}\left\{(2R_0 + Z_1) \pm \sqrt{Z_1^2 + 4Z_1(R_0 + H_0 + F V_0^2)}\right\} \quad ..(12)$$

In a similar manner, the equation for h_{t_2} is obtained by adding $F V_0^2 - F V_{t_2}^2$ under the root sign in Equation (9) and inserting the resulting value of V_{t_2} in Equation (8). Without performing the operations, which are similar to the above, the result may be written down at once.

$$h_{t_2} = \frac{1}{2}\left\{(2R_{t_1} + Z_2) \pm \sqrt{Z_2^2 + 4Z_2(R_{t_1} + H_0 + F V_0^2)}\right\} \quad ..(13)$$

Where: $$R_{t_1} = \left(\frac{a}{g} V_1 + h_1 - C_{t_1}\right)$$

$$C_{t_1} = \frac{2a}{g}(V_0 - V_{t_1})$$

$$Z_2 = \frac{\left(\frac{a}{g}\right)^2 S_{t_2}}{\left(\frac{a}{g}\right)^2 + S_{t_2} F}$$

and $$S_{t_2} = \left(\frac{a}{g}\right)^2 \left(1 - \frac{t_2}{T}\right)^2 B_0^2$$

Similarly, the value of h, at any time in any interval, may be found.

When the gate motion is not uniform, the value of S_t has to be made equal to $x^2 \left(\frac{a}{g}\right)^2 B_0^2 \left(1 - \frac{t}{T}\right)^2$, where x is a constant or variable coefficient, which may be determined by plotting the curve of gate opening on a time base. For uniform motion, the curve would be a straight line, the ordinate of which, at any time, t, is $\left(1 - \frac{t}{T}\right) B_0$. For any other than uniform motion, the ordinates of the straight line would be multiplied by the constant or variable, x, which, if the motion varied in a regular manner, might sometimes be expressed in terms of t, either graphically or analytically, from the known relation between the governor movements and the gate opening. If the motion were not regular, a graphical solution only could be obtained.

Tables 4 and 5 show the values of h_t obtained by using the formulas in the examples worked out by arithmetic integration in Tables 1, 2, and 3.

It should be noted here, by way of caution, that, in calculating the value of h, the two terms inside the larger brackets of the foregoing formulas are frequently so large and their difference so small as to make it necessary to perform the work by logarithms. The correct result cannot be obtained in such cases by using an ordinary 10-in. slide-rule.

TABLE 4.—By Formulas.

Data: $L = 820$ ft. $V_0 = 11.75$ ft. per sec. $H_0 = 165$ ft. $T = 2.1$ sec. $a = 4\,680$ ft. per sec. Friction neglected.

It is now interesting and instructive to compare the results given by the foregoing formulas with those given by other formulas which have been proposed to determine the rise of pressure caused by gradually stopping the flow of water in pipes. For this purpose, Fig. 3 has been prepared. There are three such fundamentally different formulas known to the writer, namely, those of Mr. L. Allievi,* M. M. Warren,†

* The writer was unable to obtain an English translation of Mr. Allievi's paper, but his formula is commonly given as follows:

$$h = \frac{N H}{2} + H\sqrt{\frac{N^2}{4} + N}$$

Where h = rise of pressure, in feet, above normal;
H = normal net head, in feet;

$$N = \left(\frac{L V}{g T H}\right)^2;$$

L = length of penstock, in feet;
V = velocity of water in penstock, in feet per second;
T = duration of gate closure, in seconds;
g = acceleration due to gravity, in feet per second per second.

† *Transactions*, Am. Soc. C. E., Vol. LXXIX, pp. 238, 242. Mr. Warren's formula is:

$h = \dfrac{L V}{g\left(T - \dfrac{L}{a}\right)}$, where a = velocity of the pressure wave, and the other symbols have the same significance as in this paper.

TABLE 5.—By Formulas.

Data: $L = 6\,337$ ft. $V_0 = 15.055$ ft. per sec. $H_0 = 1\,260$ ft. $T = 69.5$ sec. $a = 3\,647$ ft. per sec. Friction head, $h_f = 81$ ft.

Assoc. M. Am. Soc. C. E., and H. C. Vensano,* M. Am. Soc. C. E. The formula by Allievi gives the maximum excess pressure caused by stopping the flow of a column of water, assumed as an incompressible fluid, moving in an inextensible pipe, and neglecting the effect of friction. Mr. R. D. Johnson,† Mr. A. H. Gibson,‡ and W. F.

* *Transactions*, Am. Soc. C. E., Vol. LXXIX, pp. 289–299; and Vol. LXXXII, p. 185. Mr. Vensano's formula is:

$h = \frac{2\,l\,V}{g\,T}$, with the limitation that h can never be greater than $\frac{V\,a}{g}$.

† *Transactions*, Am. Soc. C. E., Vol. LXXIX, pp. 277–281. Mr. Johnson's formula is:

$$H_{\max.} = \frac{2\,M\,Y}{N^2}\left(M + \sqrt{M^2 + N^2}\right)$$

where $H_{\max.}$ = maximum rise of pressure, in feet, above normal; $M = L\,V$; and $N = 2\,g\,Y\,T$, in which Y is the normal net head in feet, and the other symbols have the same significance as in this paper.

‡ "Water Hammer in Hydraulic Pipe Lines", by A. H. Gibson. Mr. Gibson's formula is: (In order to prevent confusion with the foregoing, some changes have been made in the nomenclature):

$$p' = \frac{w}{g}\left[\left(\frac{L}{A}\cdot\frac{A_1}{T}\right)^2 + \frac{L}{A_1}\cdot\frac{A_1}{T}\sqrt{2\,g\,H + \left(\frac{L}{A}\cdot\frac{A_1}{T}\right)^2}\right]$$

where p' = rise in pressure, in pounds per square foot, behind the valve at the instant when closure is complete, and therefore when p is maximum;

A = cross-sectional area of penstock, in square feet;

A_1 = maximum effective area of valve opening, in square feet;

w = weight of a cubic foot of water;

and the other symbols have the same significance as in this paper.

FIG. 3.

Uhl,* M. Am. Soc. C. E., have each presented a similar formula, with different nomenclature and somewhat differently arranged, but all give the same result as Allievi's formula. Mr. Johnson has also presented a method of determining the pressure-time curve resulting from the same assumption,† and Mr. A. H. Gibson has shown how friction may be taken into account by successive calculations.‡

The limitations of the Allievi formula are well known to these authors, as they specifically refer to them; they are known, also, no doubt, to many others who use that formula, because it is readily seen that, for zero duration of closure, the formula gives an infinite pressure rise, and this cannot be so because the finite value of maximum water-hammer, for instantaneous closure, has been proved by Professor Joukovsky. Allievi's formula takes into account the effect of the net head on the phenomena that occur during closure. In Fig. 3, there are shown in dotted lines a series of Allievi curves for various heads, and, for the data assumed, these show the maximum rises of pressure as ordinates and durations of closure as abscissas. For convenience, the time abscissas have been marked off in intervals, instead of seconds. The curves, it will be noted, become very steep as the duration of closure becomes short, and, in the limit, appear to approach infinity as the duration of closure approaches zero. For low heads Joukovsky's limit of maximum water-hammer is passed by these curves at points of relatively long duration of gate closure. In Fig. 3, a similar series

* *Transactions*, Am. Soc. Mech. Engrs., Paper No. 1354. Mr. Uhl's formula is:

$$\frac{DH}{H} = \frac{n}{2}\left(n + \sqrt{n^2+4}\right)$$

where DH = rise of pressure, in feet, above normal;

$n = \dfrac{LV}{gTH}$, in which the symbols have the same significance as in this paper.

† *Transactions*, Am. Soc. C. E., Vol. LXXIX, pp. 277–281. Mr. Johnson's formulas, to be solved as indicated in his discussion, are:

$$t = T\left\{\frac{\sqrt[n]{x}-1}{\sqrt[n]{x}}\right\}$$

where $x = R\left\{\dfrac{H+\sqrt{y_0}}{J-\sqrt{y_0}}\right\}$, R being $\dfrac{J-\sqrt{Y}}{H+\sqrt{Y}}$,

and $n = \sqrt{\left(\dfrac{2gTY}{LV}\right)^2+1}$, $\quad H = \dfrac{LV}{2gT\sqrt{Y}}(n-1)$,

$$J = \frac{LV}{2gT\sqrt{Y}}(n+1)$$

FIG. 4.

of curves for various heads has been plotted from the result obtained by using the writer's formulas, and these are shown in full lines. It will be noted that these curves show maximum water-hammer for any duration of closure from zero up to one interval $\left(\frac{2\,L}{a}\right)$, and, as the duration of closure becomes longer, the resulting rise of pressure finally approaches, within certain limits, the value shown by the Allievi curve. For low heads and short durations of closure, the Allievi curves generally show higher values of pressure rise than those of the writer; but, for high heads and short durations of closure, they show lower values of pressure rise. This interesting fact will be referred to later when discussing the pressure-time curves.

The formulas of Messrs. Warren and Vensano do not include the net head as a factor, and, therefore, each may be represented, as shown in Fig. 3, by a single curve for all heads. Although these two formulas are objectionable, because they neglect the influence of the net head, it is evident, from the position of the curves representing them in Fig. 3, that under certain special conditions they will give, at least approximately, correct results. These conditions will be referred to later when discussing the pressure-time curves, but it is interesting to note here that Mr. Warren's formula gives approximately the correct results when the net head is such that the excess pressure will be a minimum for any given duration of closure. Mr. Vensano's formula gives approximately the correct result when the net head is very high with respect to the velocity destroyed.

Fig. 4 has been drawn to show the manner in which the rise of pressure varies with the net head. The results shown by the curves in Fig. 3 are plotted for a given duration of closure, ordinates representing excess pressure, but abscissas representing net head (H_0). It is thus seen that, for a given duration of closure, the excess pressure becomes less as the head increases, until at a certain value of H_0 the minimum rise of pressure is reached, and, as H_0 continues to increase, the rise of pressure also increases until it reaches a final value, when H_0 is infinite. In the example shown in Fig. 4, L is only 820 ft., and this length would represent the limit of gravity head. The curves, however, have been extended for higher heads, on the assumption, of course, that the head is produced by applied pressure. The corresponding curves obtained from the results of the Allievi, Warren, and Vensano formulas are also clearly shown in Fig. 4.

Pressure-Time Curves.

The pressure-time curves, Figs. 5, 6, and 7, show clearly the changes in pressure that take place during the closure of the gates under various typical conditions. The corresponding curves obtained from the

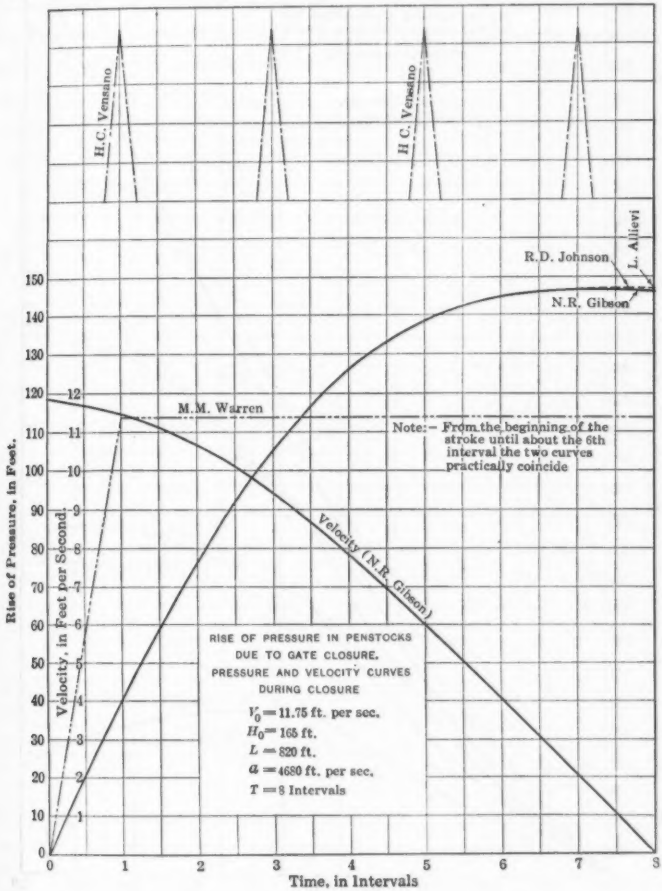

FIG. 5.

formulas of Allievi, Warren, and Vensano have been shown in these figures for the purpose of comparison with those of the writer, and in order that the various results may be studied and explained. In some

cases velocity-time curves have also been drawn, in order to show the variable rate of retardation caused by uniform gate closure.

It will be noted first that Mr. R. D. Johnson's pressure-time curve, based on Allievi's formula, or indeed Allievi's formula itself, gives the maximum pressure rise always at the end of the closing time. Mr. Warren's curve shows the excess pressure rising uniformly to a maximum at the end of the first interval and then remaining constant until

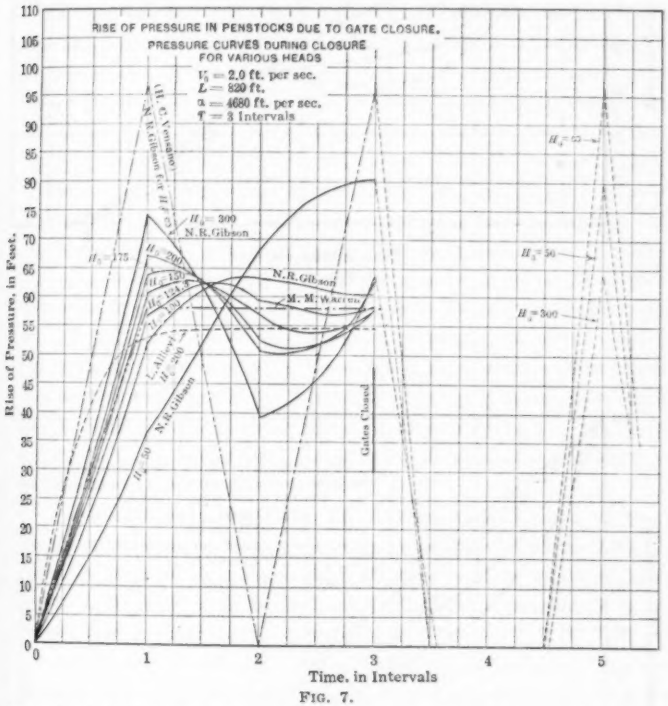

FIG. 7.

the end of the closing time. Mr. Vensano's curve shows the excess pressure rising uniformly to a maximum at the end of the first interval, falling uniformly to zero at the end of the second interval, and repeating this vibration until the end of the closing time. The writer's pressure-time curves may be similar to any one of these three, depending on the duration of closure and the net head acting on the orifice, or on both of these factors.

FIG. 9.

Commencing with Fig. 5, it is seen that the pressure-time curve, under the conditions stated, is almost identical with that given by Mr. R. D. Johnson, as far as can be detected by the eye. A careful consideration of the writer's formula, however, will reveal the fact that the pressure-time curve obtained from it is not continuous, but is made up of a series of curves, each being one interval long, and cusps or changes of curvature occur at the end of each interval. Under other conditions, the cusps are plainly visible, as, for example, in Figs. 6 and 7. For any finite conditions, these cusps, theoretically, do not disappear, that is to say, the tangent at the end of one interval never exactly equals the tangent at the beginning of the next interval. Furthermore, the slope at the beginning of the writer's curve is never exactly the same as the slope of the Johnson curve. For all practical purposes, however, the pressure-time curves shown in Fig. 5 (and numerous other curves for similar conditions) are almost identical, and the maximum pressure rise occurs in both of them at the end of the stroke. This is interesting because the two theories from which the respective formulas are derived are totally different. When the conditions are such as to produce practically identical pressure-time curves similar to the foregoing, it indicates that the effect of the compressibility of water, the elasticity of the pipe walls, and the resulting harmonic vibrations in the water column may be neglected, and in such cases the assumptions, on which the Allievi formula has been based, are practically sufficient.

The results obtained from the Warren and Vensano curves are much at variance with the foregoing, as indicated in Fig. 5, and the writer is of the opinion that neither of these formulas can apply for all values of H_0, and, only under certain conditions, which will be mentioned later, are they approximately correct.

As shown in Fig. 3, the maximum pressure rise given by the writer's formulas, as would be expected, is nearly always less than that given by the Allievi formula when the duration of closure is short and when $\frac{H_0}{V}$, the ratio of head to velocity destroyed, is small. When the ratio of head to velocity destroyed is large, the reverse is the case, and, when H_0 becomes infinitely large, the writer's formulas agree with that of Mr. Vensano and give results twice as great as Allievi's formula for any finite duration of closure greater than one interval. Even

when the values of maximum pressure rise, as given by the Allievi formula, are in close agreement with those of the writer, both for short and long durations of closure, the respective shapes of the pressure-time curves may be different. Figs. 6 and 7 show clearly the characteristics of the pressure-time curves in a number of typical cases, and a close study of them, together with Fig. 4, will make clear the relation that exists between the rise of pressure and the net head for any velocity destroyed. The shapes of the pressure waves that continue after the gates have been closed, until damped out by friction, are also indicated in Figs. 6 and 7.

Referring now to Fig. 7, it will be noted that the particular case when Mr. Warren's formula gives approximately correct results is when the head is such that the rise of pressure due to gate closure is a minimum for the particular velocity destroyed. This occurs when $H = \frac{3}{7}\frac{aV}{g}$.

Fig. 7 shows, also, the shapes of the pressure-time curves for various heads, and indicates the variation in time when the maximum pressure occurs during closure.

The foregoing examples, except Tables 2 and 5, have all been calculated for uniform gate motion. As the writer's formulas may be applied for any variable rate of gate motion, it is interesting to determine the nature of the gate motion for various heads that would be required to produce diagrams similar to those proposed by Messrs. Warren and Vensano. A diagram of the shape proposed by Mr. Warren may be produced by the simple expedient of increasing the speed of gate travel at the end of the first interval to double the rate of its motion during the first interval and maintaining this double rate until the end of the stroke. Such an operation, though giving the same shape to the pressure-time diagram, will not give, of course, the same rise of pressure as for the same duration of uniform closure, but the latter is given by a gate motion similar to that shown in Fig. 9. If a pressure-time diagram of the same shape as Mr. Vensano's is desired for a low head, a very complicated gate motion would be required, such, for example, as that shown in Fig. 8. In a similar manner, the gate motion required to produce any suggested form of pressure-time curve may be determined.

The manner in which excess pressures vary from gate to origin has been explained in Miss Simin's translation of Professor Joukovsky's paper, although therein worked out on the erroneous assumption of uniform retardation of the velocity of the water flowing in the pipe.

O. V. Kruse, Assoc. M. Am. Soc. C. E., who was associated with the writer at the time this paper was first written, has made an original study of the variation in excess pressure from gate to origin, based on the writer's application of Joukovsky's theory to slow-closing gates. The results of this study, which will appear as a discussion, together with other comments from him, prove that when the duration of uniform closure is less than $\frac{2L}{a}$, the maximum pressure is exerted along the pipe to a point where the distance to the origin is equal to $\frac{Ta}{2}$. From that point to the origin the pressure reduces uniformly to zero. When the duration of uniform closure is equal to, or greater than, $\frac{2L}{a}$, the maximum rise of pressure occurs at the gate, and from there to the forebay or origin reduces to zero, uniformly along the length of the pipe.

Fall in Pressure.

Professor Joukovsky's theory of pressure waves applies also to the fall in pressure produced by opening a valve or gate at the end of a pipe line, and the application of his theory to the case when a valve is gradually opened may be made in a similar manner to the foregoing. It is obvious, of course, that the fall in pressure caused by opening a valve in a certain time is not precisely the same as the rise in pressure caused by closing the valve in the same time, because the rate of acceleration cannot be the same as the rate of retardation. It would lengthen this paper unduly, however, to do more than state here that the formulas for fall in pressure may be obtained in a similar manner to those given herein, the principles being the same in both cases.

Experimental Results.

The writer has not yet had an opportunity of testing the formulas presented in this paper by experiments, to show, not only the correctness of the values of maximum pressure rise, but also the shapes of the pressure-time curves under various conditions. It is expected, however,

that an opportunity of doing so may possibly occur in the not too distant future. In the meantime this paper is presented in the hope that it will receive criticism or confirmation from those interested in the subject.

The experimental results obtained by Mr. Vensano, and presented in his paper entitled "Pulsations in Pipe Lines", give some striking confirmation of the correctness of the writer's formulas, not only as regards the maximum pressure rise, but also as indicating the resemblance between the calculated and observed pressure-time curves, both before and after the gate was completely closed, and at various points along the pipe line, as well as at the gate.* These, however, were carried out under a very high head (1 260 ft.), and could hardly be accepted as a general proof.

The writer also proposes to show how the pressure-time diagram may be used to determine the velocity of flow in a pipe, for the purpose of measuring the rate of discharge previous to the closing of the gate. This will be made the subject of another paper to be written at a future time.

In conclusion, the writer desires to accord credit to Mr. O. V. Kruse for the valuable help he has given in the preparation of this paper, to Mr. R. L. Hearn for the work of preparing Figs. 8 and 9, and to Mr. R. D. Johnson for the many helpful suggestions he has kindly made.

* See discussion by Norman R. Gibson in *Transactions*, Am. Soc. C. E., Vol. LXXXII, p. 236.

DISCUSSION

Mr. Kruse.

OTTO V. KRUSE,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer has studied the phenomena of water-hammer, and offers a short analysis of Miss O. Simin's translation of Prof. Joukovsky's notable work, and an elaboration of certain parts of Mr. Gibson's paper.

Any pipe under pressure and containing water in motion may be assumed as a unit of energy under a condition of equilibrium. If we wish to stop the column of water, it means the application of a certain amount of force during a certain time to bring about the conversion of energy and restore the equilibrium. In analyzing the phenomena which take place, the writer believes that the most important point to study is the rate of destruction of velocity as affected by the net head, because this determines to a large extent the rate of pressure rise and hence the maximum pressure rise. Apparently, Allievi used this as a basis for the development of his formula, and this, of course, applies to Johnson's formula, which is the same as Allievi's. Any formulas, such as Warren's and Vensano's, which do not take this into account must be incorrect, except for one set of conditions. The curves given by Mr. Gibson show how far from the truth they may be.

In accordance with the ordinary methods of integration, it may be considered that the gate movement throughout the duration of the stroke is made up of an infinite number of small instantaneous movements. In the case of the formulas of Allievi and Johnson, which involve the dynamic forces, each little movement of the gate produces a pressure:

$$h = \frac{L\,dv}{g\,dt}$$

The conditions existing, then, at the end of any small movement are:

1. The original velocity has been decreased by the amount of the velocity destroyed during this first movement;
2. A dynamic pressure has been created, due to the destruction of velocity.

A new velocity now exists, which is dependent, not on the original net head, but on a new head made up of the original net head and the dynamic head. As brought out by Mr. Johnson, these curves of dynamic pressure rise and decrease in velocity may be calculated by a simple method of arithmetic integration, using only the relation, $h = \frac{L\,dv}{g\,dt}$. The Allievi or Johnson formula will give a figure for maximum pressure rise, and Mr. Johnson has also developed a formula for the shape

* Philadelphia, Pa.

Mr. Kruse.

of the pressure curve, these formulas giving the same results as can be obtained approximately by arithmetic integration.

The question to be considered now is: To what extent, and how, do the compressibility of water and extension of the pipe walls affect the pressure and velocity curves? We know that, as the time of closing grows shorter, the Allievi formula approaches infinity. On the other hand, Joukovsky proved that the maximum pressure which obtained for instantaneous closing depended on the velocity destroyed and the speed of propagation of the pressure wave, and could not exceed "maximum water-hammer." It is not difficult to see that, for a long closing time, the compressibility of the water and extension of the pipe walls have very little effect on the maximum pressure, but, as the time of closing grows shorter, the properties of the materials have a greater and greater effect. The writer believes that Mr. Gibson's formulas have successfully supplied this missing gap between Allievi's and Joukovsky's theories, and serve to give correct results for all conditions.

Professor Joukovsky made a great many experiments to determine the magnitude of maximum water-hammer and the speed of propagation of the pressure wave, all based on instantaneous closing of the gates. The details of the experiments will not be given here, but the following is a synopsis of the theory, taken verbatim from Miss Simin's translation:

"In Fig. [10] let A B be a pipe, in which water flows with velocity, v, from the origin A, past the gate, B. If, now, the flow is suddenly stopped by a rapid shutting of the gate, B, the kinetic energy of the water column, A B, will cause an increase of pressure in the pipe.

"Let us consider the column of water, A B, as divided into n very small equal sections, 1, 2, 3,....(n — 1) and n.

"The phenomena of water-hammer take place in a series of cycles, each consisting of four processes, as follows:

"(1) Section 1, meeting, in the gate, an obstacle to its movement, will be compressed and will stretch the pipe wall surrounding it. All the kinetic energy of this section of water will be used up (a) in its own compression, resulting in the increase of pressure by an increment, P, and (b) in the corresponding stretching of the walls in section 1 of the pipe. As a result of this action, section 1 of the water column has left vacant behind itself a small space, to be occupied by a part of the next arriving section 2. Consequently it is only after section 1 has been stopped and compressed, and after the small space thus left has been filled, that section 2 can be arrested and compressed.

"Now the kinetic energy of section 2 must be expended in some way. Will it increase the pressure upon the gate, which has already been caused by the arrest of section 1? No, and for the following reason:

"The pressure upon the gate depends entirely upon the pressure, P, sustained by section 1, which is now in static condition.

"The pressure upon the gate could therefore be increased only if section 1 could be further compressed, and this could take place only

if the pressure upon the surface between it and section 2 (which we may imagine to be a thin piston) could be greater from the side of section 2 than it is from the side of section 1; and this is impossible, because section 2 has only the same kinetic energy as section 1, and this energy will (as in the case of section 1) be used up entirely in compressing the water of the section (section 2) only to the same additional pressure, P, and in stretching that part of the walls surrounding section 2. Mr. Kruse.

"The same is true of each following section, 3, 4,.... $(n-1)$ and n; each of these sections, as it is arrested, being compressed to the pressure, P.

"During process (1) a small quantity of water flows from the reservoir into the pipe, to occupy the space formed by the compression of the water and the extension of the pipe walls.

"Finally, when all the sections have been arrested, the entire column will be under the pressure, P. The entire energy of the water column is now stored (as potential energy) in elastic deformation, viz., in the compression of the water column and in the extension of the pipe walls.

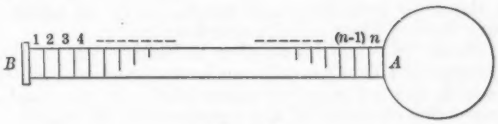

FIG. 10.

"But this condition cannot be maintained; for

"(2) As soon as the additional pressure, P, has been produced in the last section, n, the water in that section will again expand, and the walls of that section of the pipe will again contract, restoring the original conditions in that section, and pushing the water of that section back into the reservoir from which the pipe issues, and restoring the original normal pressure in section n.

"This operation will now be repeated by each section $(n-1)$,....4, 3, etc., in turn, until all the potential energy, stored in the water column when it was under the pressure, P (neglecting the portion lost in friction), has been reconverted into kinetic energy.

"During process (2) the water which entered the pipe during process (1) is forced back into the reservoir.

"The condition of the water column is now what it was just before the gate was closed, except that its velocity, v, has now the opposite direction, *i. e.*, toward the origin.

"(3) The kinetic energy of the water column, moving toward the origin or away from the gate, is now reconverted into potential energy, which manifests itself in an extension of volume of the water to a subnormal pressure beginning with section 1, and concluding only when the entire water column has been reduced to the subnormal pressure.

"During process (3) water continues flowing from the pipe into the reservoir.

"(4) When the subnormal pressure has been established throughout the length of the pipe, and all the water has come to rest, the water from the reservoir will again direct itself into the pipe, restoring

Mr. Kruse.

the normal pressure, first in section n, next to the reservoir, and then, in rapid succession, in the other sections $(n - 1), \ldots 4, 3$, etc., until, when the normal pressure reaches the gate, we have once more the conditions which existed just before the gate was closed, viz., the normal pressure is restored and the water is moving toward the gate with the original velocity, v.

"We have now followed these pulsations of pressure (with the accompanying transformations of energy and flow of water into and back from the pipe) through a complete cycle of four movements, each extending through the length of the pipe. For convenience, we may consider two successive movements of this kind as a 'round trip' through the pipe.

"The gate remaining closed, the whole process is now repeated in a second cycle, which, in turn, is followed by a third, and so on, the amplitude of the pressure vibrations gradually diminishing (because of friction) until the pipe and the water come to a state of rest.

"But although the intensity of the pressure becomes gradually less, the time required for each cycle remains constant for all repetitions.

"This propagation of pressure, consisting of its transmission through all points of the length of the pipe, each point successively repeating the same periodical movements, is, in its nature, simply a case of wave motion, like that of a sound wave.

"The velocity of wave propagation is independent of the intensity of the pressure, and depends only upon the properties of the medium through which the propagation takes place—in the case of water-hammer, upon the elasticity of the water and of the pipe."

Mr. Gibson has applied this theory to slow-closing gates by considering that each infinitesimal movement of the gate is instantaneous and produces a small rise of pressure which travels through the penstock in the same manner that a wave produced by total instantaneous closing would travel. These small gate movements occur in succession and produce in turn their pressure waves which travel back and forth through the penstock. An algebraic sum of these waves gives the rise of pressure existing at any time during the closing stroke.

The writer is of the opinion that the pressure existing throughout the length of the pipe for a slow-closing gate varies almost directly from a maximum at the gate to zero at the point of relief, except where the time of closing is less than $\frac{2L}{a}$.

In Fig. 11, the pressure existing at four points on the penstock has been plotted. The magnitude of the individual pressure waves is not to scale, but their values are shown for the particular example taken. The pressure existing at a point $\frac{L}{2}$ from the gate is approximately one-half the pressure existing at the gate. The pressure existing at a point $\frac{3L}{4}$ from the gate is approximately one-quarter of the pressure existing at the gate.

Mr. Kruse.

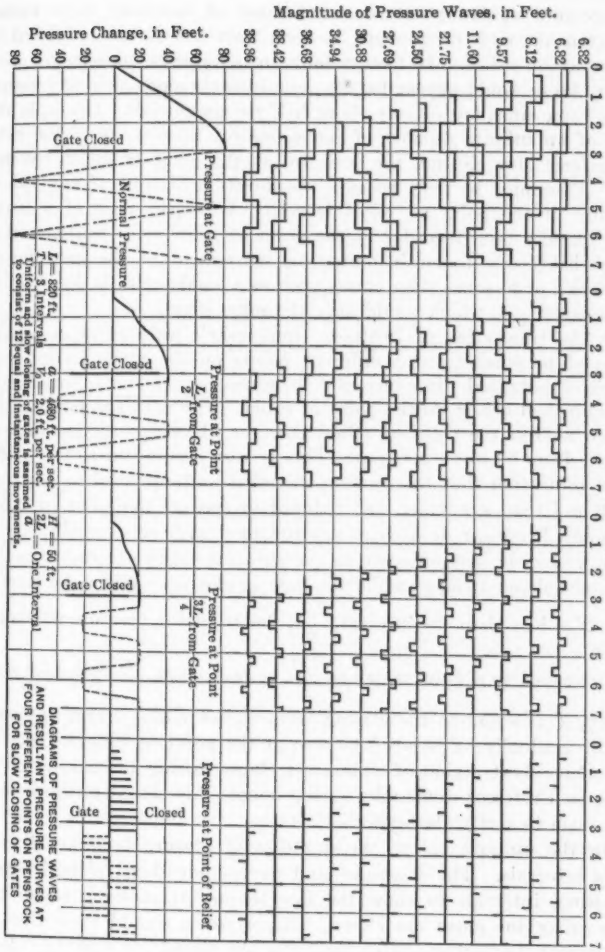

FIG. 11.

Mr. Kruse.

The diagram showing the pressure existing at the point of relief consists of a series of instantaneous rises above normal. On account of the assumption of twelve instantaneous movements of the gate, the pressure at the point of relief must of necessity show twelve instantaneous rises of pressure, as each wave travels undiminished to the point of relief. If twenty-four instantaneous movements were chosen, there would appear twenty-four instantaneous rises of pressure in the same time, but of only about half the magnitude. Hence, in the limit of an infinite number of instantaneous movements of the gate, or uniform slow-closing, the pressure at the point of relief becomes zero. This must be true, because the duration of time of any rise of pressure at the point of relief is zero. Wherever rises of pressure have actually been recorded at the point of relief on a penstock, they are probably due to an instantaneous movement of the gate during the stroke, or to some other cause, such as a sudden elastic deformation of the waterway, which would have the same effect.

In the translation of Professor Joukovsky's work there are shown tables of pressure rises at different points on the pipes for different velocities destroyed. In every case the pressure waves travel practically undiminished almost to the point of relief. The readings taken at the station nearest the point of relief, however, show a reduction in pressure of from 60 to 80 per cent. This is very significant to the writer, as an indication that the pressure traveled undiminished to a certain point and then gradually was reduced to zero at the point of relief. Although Professor Joukovsky experimented with very rapidly closing gates, as nearly instantaneous as possible, obviously a certain fraction of a second must elapse while the gate is closing. When the time of closing is less than one interval, $\frac{2L}{a}$, the resultant pressure will travel undiminished to a point which is $\frac{Ta}{2}$, in feet, from the point of relief (where T is equal to the closing time, in seconds). From this point it will gradually be reduced to zero at the point of relief. Granting that some short period of time must elapse during the closing of the gates in Professor Joukovsky's experiments, his actual pressure readings seem to verify the writer's claim.

In the example taken, the duration of closure is assumed to be three intervals. The diagrams and curves have been plotted beyond the three intervals to show the fluctuations of pressure which take place after the gates are closed. Experiments should show that the subsequent fluctuations after the gates are closed are quickly reduced in intensity by internal friction, but this friction should have no effect on the speed of propagation of the pressure waves. Internal friction has of necessity been omitted in these computations, as it is an unknown quantity.

Any other example than that shown by Fig. 11 may be chosen, and the pressure waves may be computed by Mr. Gibson's formulas. A series of diagrams may then be plotted, similar to those shown by the writer, and the pressures may be computed for any point on the penstock. Mr. Kruse.

In making the computations for the magnitude of the pressure waves, it is necessary to determine first the number of intervals of time $\left(\text{equal to } \frac{2L}{a}\right)$ contained in the total closing time. The gate movement may then be divided into a number of instantaneous movements equal to the number of intervals. Computations carried out on this basis will give correct points on the pressure-rise curve at the end of each interval. In the event of the closing time being only a few intervals, it is desirable to subdivide the gate movement further in order to develop the curve during the intervals. It is an interesting fact, however, that such further subdivision of gate movement serves only to develop the shape of the curve during the intervals, and has no effect on the values at the end of each interval. In making studies of this character, it is often easier instead of using Mr. Gibson's formulas, to utilize the system of arithmetic integration, which will give correct results, although involving trial-and-error methods.

In order to compute the pressure-rise curve at points on the penstock other than at the gate, the gate movement must be divided into a number of divisions sufficient to cause the pressure waves to overlap. Thus, at least two divisions per interval must be used to compute the curve at a point half way up the penstock, at least four divisions per interval for a point three-quarters of the way up the penstock, and at least eight divisions per interval for a point seven-eighths of the way up the penstock. Referring to Fig. 11, where four divisions per interval were chosen, it is obvious that the pressure beyond the point, $\frac{3L}{4}$ from the gate, cannot be computed without a greater subdivision of the gate movement.

In this discussion the writer has endeavored, principally, to point out the trend of argument and application of existing data used in proving the theoretic correctness of Mr. Gibson's method of handling water-hammer problems. The method seems to be fundamentally sound, and deserves the careful thought of engineers.

EUGENE E. HALMOS,* ESQ. (by letter).—Ever since the publication of the paper† entitled "Penstock and Surge-Tank Problems" by Minton M. Warren, Assoc. M. Am. Soc. C. E., the writer has hoped that some one, preferably a member of the Society, would point out Mr. Halmos.

* Designing Engineer, Barclay Parsons and Klapp, New York City.
† *Transactions*, Am. Soc. C. E., Vol. LXXIX, p. 238.

Mr. Halmos.

the injustice done to one of the greatest hydraulic engineers of the present age by the form of, and the comments appended to, Mr. Warren's presentation of what he termed "Alliévi's formula."

Unfortunately, Mr. Warren has not been corrected. This formula was accepted by American engineers as representing Alliévi's solution of the problem of water-hammer in pipe lines, and, consequently, it has been severely criticized and misinterpreted.

The value of Mr. Gibson's excellent paper is also seriously impaired by the references, both in the text and in the diagrams, to "Alliévi's formula" as taken from Mr. Warren's paper, and the writer would suggest that, after perusal of the following, Mr. Gibson omit all reference to Alliévi, except to state that his solution agrees, in every particular, with that of Alliévi.

The writer proposes to submit a brief summary of Mr. Alliévi's formulas, which, in his judgment, represent a complete solution of water-hammer problems as regards determination of the pressure at the gate or at any other section of the conduit, at any instant, and under any conditions of closure and physical characteristics of the plant. It is more general than Mr. Gibson's solution, inasmuch as it also includes the determination of the pressure variations after the stopping of the gate movement, and as it gives a method of estimating the interval in which the pressure maximum will occur.

As the present paper and the previous ones deal almost exclusively with the case of water-hammer during the closure of gates, and with the variation of the pressure at or near the gates, the writer will only quote Alliévi with regard to formulas applicable to such cases. The writer, however, intends to translate Alliévi's book into English, which, it is hoped, will be of great help to designers of hydraulic plants and apparatus.

In the following, the formulas representing the relation of time and pressure are given for three phases, namely:

the first phase, for which $t \leqq \frac{2L}{a}$;

the second phase, for values of t beginning with $t = \frac{2L}{a}$ and ending at T;

and the third phase, $t > T$.

Notation.—

a = velocity of propagation of pressure along pipe;

c_0 = uniform velocity of water in pipe before beginning of gate closure;

C = variable velocity of water in pipe at any instant during gate closure;

u_0 = uniform velocity of water through gate orifice before beginning of closure; Mr. Halmos.

u = variable velocity of water through gate orifice during gate closure;

t = time, in seconds, recorded from beginning of gate movement;

T = duration of gate movement, assumed to be continuous;

L = length of pipe conduit;

y_0 = pressure head on pipe line at gate before closing begins;

y = variable head at gate due to closure.

A.—General Formulas.

(1) *Variation of Pressure Head During and After the Closing Motion of the Gates.—*

First phase, $t \leq \frac{2\,L}{a}$.

For this interval, the pressure head, y, at any instant can be computed from the equation

$$y^2 - 2\,y\left(H + \frac{a^2\,\psi^2\,(t)}{g}\right) + H^2 = 0 \quad \ldots\ldots\ldots\ldots (1)$$

in which $$H = y_0 + \frac{a\,c_0}{g}$$

and $\psi\,(t)$ is the ratio of the instantaneous area of discharge to the (assumed) constant area of the penstock, that is, $\psi\,(t) = \left(1 - \frac{t}{T}\right)\frac{c_0}{\sqrt{2\,g\,y_0}}$ the value of $\psi\,(t)$ being taken at the instant for which the pressure head, y, is calculated.

It will be noted that if the gate is closed in a time, $T \leq \frac{2\,L}{a}$, $\psi\,(T) = 0$, and the equation reduces to

$$y^2 - 2\,H\,y + H^2 = 0$$

$$y = H = y_0 + \frac{a\,c_0}{g} \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

which shows that in such a case the maximum pressure head is independent of the actual length of the time of closure.

Of the two roots of Equation (1) one is greater, the other is smaller, than H. This latter is the true value of the pressure head at any instant.

Second phase, $\frac{2\,L}{a} \leq t \leq T$.

Mr. Halmos.

During this period of the gate movement, the following equation applies for the determination of the pressure head at any instant:

$$y^2 - 2y\left(H - 2f + \frac{a^2 \psi^2(t)}{g}\right) + (H - 2f)^2 = 0 \ldots\ldots (3)$$

Of the two roots of Equation (3), that giving the smaller value should be used.

It will be noted that this equation differs from Equation (1) only in so far that, instead of H in the latter, $(H - 2f)$ appears in Equation (3).

The values of the function, f, should be determined in the following manner:

For the interval, $0 < t < \frac{2L}{a}$, $y - y_0 = F(t)$, y being calculated from Equation (1).

The velocity, C, in the conduit (at the gate) can be computed from the equation

$$y + \frac{a}{g} C = H$$

for this interval.

For the interval, $\frac{2L}{a} < t \leqq \frac{4L}{a}$, $f = F\left(t - \frac{2L}{a}\right)$; in other words, the values of $F(t)$ found in the first interval should be substituted for f in Equation (3) to obtain the value of y for every subdivision of the second interval. Then, the corresponding values of the velocity, C, may be found by $y + \frac{a}{g} C = H - 2f$, and the value of $F(t)$ for the second interval by $F(t) = \frac{a}{g}(c_0 - C) - f$.

For the third interval, $\frac{4L}{a} < t \leqq \frac{6L}{a}$, the values of $F(t)$ so found for the subdivisions of the second interval should be substituted for f in Equation (3) to get y, and so on, for all subsequent intervals until the gate has stopped moving or has become entirely closed.

Third phase, $t > T$.

If the movement of the gate is stopped at an instant such that $t_1 < \frac{2L}{a}$, the pressure head, y, remains constant until $t = \frac{2L}{a}$. From this instant on, or from the time of the stoppage, in the case, $t_1 > \frac{2L}{a}$, there is developed a hydrodynamic phenomenon in the form of an asymptotical approach of the pressure head, y, to the new constant head, y_0, of uniform flow. There are three different cases.

First.—If $a\ \psi\ (t_1) > \frac{u_0 + u_1}{2}$, in which case y approaches y_0 without oscillations.

Second.—If $a\ \psi\ (t_1) < \frac{u_0 + u_1}{2}$, in which case y approaches y_0 through oscillations of diminishing amplitude.

Third.—If the gate is entirely closed, $\psi\ (t_1) = 0$, the pressure head (disregarding the dampening effect of hydrodynamic friction) oscillates indefinitely, with a constant amplitude, between the value of y, which occurs at the instant of closing, and $2\ y_0 - y_1$, the amplitude being $y_1 - y_0$.

(2) *Estimating the Phase in Which the Maximum Pressure Will Occur.*—Assuming a linear closure of the gates:

(a) If $a\ c_0 < 2\ g\ y_0$, then the pressure head at the end of the first phase $\left(t = \frac{2\ L}{a}\right)$ will always be greater than the average maximum pressure (found by Equation (4)) occurring during the second phase.

(b) If $2\ g\ y_0 < a\ c_0 < 3\ g\ y_0$, the maximum pressure head occurs either at the end of the first phase, or during the second phase, according to whether the closing time, T, is smaller or greater than

$$\frac{a\ c_0 - g\ y_0}{a\ c_0 - 2\ g\ y_0} \cdot \frac{L}{a}.$$

(c) If $a\ c_0 > 3\ g\ y$, then the maximum pressure will always occur during the second phase and will be greater than that at the end of the first phase.

Equations (1), (2), and (3) are the general formulas derived by Alliévi, by the help of which complete pressure-time curves can be worked out for any assumed conditions of T, L, a, c_0, and y_0. The writer is very much pleased to state, that, by the use of these equations, he was able to check accurately all the curves presented by Mr. Gibson. He wishes to compliment the author in having found, quite independently, and by a simpler mathematical method than Alliévi's functional derivation, the correct formulas for the representation of pressure-time curves and related phenomena.

B.—Special Formulas.

It has been found by experiment, and by working out pressure-time curves for a great number of cases actually met in practice, that, on the assumption of linear gate closure:

(d) The pressure behind the gate remains practically constant for $\frac{2\ L}{a} < t \leqq T$ (y is not a function of time or $\frac{d\ y}{d\ t} = 0$ between

Mr. Halmos.

these limits) and, therefore, for this period, the pressure is independent of the elastic qualities of the water and the conduit, in other words, independent of (a);

(e) The pressure is distributed in a linear way along the pipe;

(f) The velocity of the water, C, is the same at any instant at any section of the conduit $\left(\frac{d\,c}{d\,x}=0\right)$.

Taking into consideration the observations noted under (d), (e), and (f), a good average value of y maximum during the second phase can be obtained by solving the equation

$$Z^2 - Z\,(n^2+2) + 1 = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

where $$Z = \frac{y_{max.}}{y_0} \text{ and } n = \frac{c_0\,L}{g\,T\,y_0}.$$

This equation is identical with Equation (C) in Mr. Warren's paper. In order that it should be valid, it is necessary:

(1) That T be greater than $\frac{2\,L}{a}$;

(2) That the gate movement (the rate of reduction of the area of the outlet) be a linear function of the time;

(3) That, in case of partial closure, that value of T should be used which would be obtained if the gate should be completely closed at the same rate of speed;

(4) That the physical data, as L, a, y_0, and c_0, shall conform to those ordinarily met in practice.

In order that Equation (4) should produce the maximum pressure head obtaining during the whole movement of the gate, it is necessary that $a\,c_0$ shall take the values defined under (b) and (c).

It is evident that Mr. Warren committed a serious error by omitting the publication of Alliévi's general Equations (1), (2), and (3), and by omitting the proper definition of Equation (4) and the limitations of its applicability as defined by Alliévi.

The only ambiguity which may occur in using this formula is the lack of a better definition of Condition (4). This is extremely difficult, on account of the great number of variables entering into the problem. The writer, however, proposes, without being able to give strict analytical proof at the present time, that Equation (4) should be used only, if

(α) $$\frac{L\,c_0}{g\,T\,y_0} < \frac{1}{2}\sqrt{\frac{a\,c_0}{y_0\,g} + \frac{y_0}{y_0 + \frac{a\,c_0}{g}}} - 1;$$ and,

(β) $$a\,c_0 > 2\,g\,y_0.$$

Mr. Halmos.

As L, c_0, a, and y_0 are dependent on rather unalterable physical conditions, if Condition (β) is satisfied, Condition (α) can be fulfilled by determining T according to the proposed formula.

If, besides Conditions (α) and (β), Conditions (b), (c), (1), and (2) are also fulfilled, Equation (4) will give the absolute maximum head at the gate during the movement of the apparatus.

It will be found that,

$$\text{for } c_0 \geqq 10 \text{ ft. per sec.}$$

$$y_0 = \text{between 100 ft. and 500 ft.}$$

$$T \geqq 6 \text{ intervals,}$$

all the foregoing conditions are fulfilled, which means that, in most practical cases, Equation (4) actually furnishes the maximum pressure head at the gate.

If the elasticity of the water and the conduit is neglected for the whole time of the movement of the gate, then, for the conditions for which Equation (4) is applicable, the pressure-time curve can be platted from the equation:

$$\log. \frac{\left(\sqrt{u_0^2 + u_R^2} + u - u_R\right)\left(\sqrt{u_0^2 + u_R^2} - u_0 + u_R\right)}{\left(\sqrt{u_0^2 + u_R^2} - u + u_R\right)\left(\sqrt{u_0^2 + u_R^2} + u_0 - u_R\right)} = \frac{\sqrt{u_0^2 + u_R^2}}{u_R} \log. \frac{T}{T - t} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

in which $u_R = K \frac{L}{T}$, where K is the ratio of the area of the gate opening at $t = 0$ to the area of the pipe, and

$$u_0 = \sqrt{2 g y_0}, \quad u = \sqrt{2 g y}.$$

This curve will have a maximum at $t = T$ if Conditions (b) and (c) are fulfilled, and will have a practically horizontal position in the second phase if Condition (α) is observed. It will differ very little from the true curve of pressure variations, and is applicable to practically the whole range of actual water-power problems.

It will be noted that Equations (4) and (5) are identical with Equations (6) and (7) given by Mr. R. D. Johnson in his discussion* of Mr. Warren's paper. Great credit is due to Mr. Johnson for having grasped correctly the essential features of this difficult subject, and for his wonderful mathematical skill in solving by independent methods the intricate problem of water-hammer.

In conclusion, the writer wishes to observe, that it would be desirable to encourage the use of Alliévi's, Gibson's, and Johnson's formulas for

* *Transactions*, Am. Soc. C. E., Vol. LXXIX, p. 280.

Mr. Halmos. water-hammer, and to reject and discourage the use of other formulas, some of which, such as Mr. Warren's, are never true, not even accidentally.

Mr. Johnson. R. D. JOHNSON,* ESQ. (by letter).—Mr. Gibson's remarkable paper deserves the closest attention on the part of all who are interested in the water-hammer problem.

He remarks that the theory has not been experimentally confirmed, but it is so obviously complete and correct as scarcely to need such confirmation to establish strong faith in its accuracy.

The writer has been especially interested in a completely correct treatment of this subject, in order to be able to fix the limits of K within which his pressure-time curve, previously presented to the Society, is sufficiently accurate for practical purposes.

It is found, fortunately, that this smooth curve,† $\log. x = n \log. \frac{T}{T-t}$, is applicable with much precision to such a wide range of conditions as to justify its use for practically all the water-hammer problems arising in connection with the design and operation, under ordinary heads, of water turbines, when properly regulated.

By differentiating Mr. Gibson's equations, it is possible to express rigidly correct values of the tangents to the true pressure-time curve at (a), the beginning of gate closure, (b), the end of the first interval, and (c), the beginning of the second interval.

Using Mr. Gibson's nomenclature, with omission of subscripts, that is, putting $R_0 = R$, and $S_{T_1} = S$, and $H_0 = H$, these tangents may be expressed as follows:

$$\text{tan. } (a) = \frac{2\,R\,H}{(R+2\,H)\,T}$$

$$\text{tan. } (b) = \frac{R^2\,(T-T_1)}{H\,T^2}\left\{\frac{S+2\,R+2\,H}{\sqrt{S\,(S+4\,R+4\,H)}}-1\right\}$$

$$\text{tan. } (c) = \frac{R^2\,(T-T_1)}{H\,T^2}\left\{\frac{S\,(Z+1)+2\,R+2\,H}{\sqrt{S\,(S+4\,R+4\,H)}}-(Z+1)\right\}$$

$$\text{where } Z = \frac{4\,H^2\,T}{R\,(R+2\,H)\,(T-T_1)}.$$

It is clear that the effects of vibration in the water column, due to elasticity, tend to disappear when the conditions are such that tan. (b) and tan. (c) approach equality; also, if the change in the rate of pressure rise at the beginning of the second interval, due to the effect of

* New York City.

† The derivation of this curve, Equation (7), is given in *Transactions*, Am. Soc. C. E., Vol. LXXIX, p. 280.

the returning wave, is less than the rate at which the pressure begins to rise when the gate starts to move, it is evident that the conditions are such that the effect of elasticity is rapidly dying out, and that it should be scarcely appreciable during the remainder of the closing period. Mr. Johnson.

If, then, tan. (b) — tan. (c) < tan. (a), the writer's Equation (7), above referred to, or the maximum value of h, given by the so-called Alliévi formula, may be used with much precision.

This may be shown to be the case when,

$$K > \frac{2}{\sqrt{3\,r^2 + 1} - 1} \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

where r is the ratio, $\frac{T - T_1}{T}$; and $K = \frac{R}{H}$.

Formula (1) marks the lower limit for values of K, below which it is not safe to use Equation (7). To find the upper limit of safety, for values of K, it is noted that, as H decreases, the pressure-time diagram passes through a transition stage where an ogee form of curve most closely approaches to a straight line, and, that thereafter, as H continues to decrease, Equation (7) begins to produce a curve sharply upturning and curving one way, for the most part, as its extremity reaches toward infinity, thus leading to serious errors in its results.

By trial, assisted by arithmetic integration, it has been noted that, for large values of n, the head may be reduced to about one-half the value which produces the approximate straight-line diagram.

To find this point we may equate the value of h_{max} in the so-called Alliévi formula to the value of the pressure rise found at the end of a straight-line pressure-time diagram, enclosing the same impulse area, and solve for the value of H.

In this way it is found that

$$K = 3n \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

(where n is the closing time expressed in intervals), and Equation (7) may be used so long as

$$K = \text{or} < \frac{6\,n^2}{n + 1} \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

which, for large values of n, is nearly twice as great as the value given by Formula (2), but which becomes equal to 3, as it necessarily must, when n becomes unity.

Formula (3) marks the upper limit for values of K, above which it is not safe to use Equation (7). Therefore, the smooth logarithmic curve given by Equation (7) may be applied only when K lies between the values given in Formulas (1) and (3), and preferably, also, when n is not less than three intervals.

Mr. Johnson.

Fig. 12 shows that Equation (7) covers a very wide range of conditions, and, furthermore, in the design of a water-turbine installation, the values of V and n should, when possible, be adjusted so that Equation (7) will be correctly applicable; and particular attention should be given to the limitations set forth in Formulas (1) and (3), in order that the speed of the water unit may be regulated most effectively.

The expressions for the tangents, (a), (b), and (c), are rigidly accurate, and form a substantial basis for further possible study; for example, if tan. (c) be equated to zero, the limiting value of n may be found when the maximum pressure rise occurs at the end of the first interval. This is thus found to be the case, always, when

$$n > \frac{4\,K^2 + 8\,K}{12 - K^2 - K^3} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

It is seen that this expression is positive and finite only so long as $K < 2$; therefore, K must always be less than 2, in order that the maximum rise shall occur at this point. It does not follow that this will be the case merely because $K < 2$, unless Formula (4) also applies.

In support of Mr. Gibson's work by experimental observation, it may be pointed out that much information is available for cases which occur within the limits here set forth, and, inasmuch as his complete work incidentally includes such cases, it may safely be predicted that no error in theory will be discovered by experiment.

The writer, himself, has confirmed Equation (7) a great many times, under a variety of conditions, in the past twenty years, and, because of such confirmation, he was not led, from practical necessity, to a more thorough investigation of the theory.

In conclusion, the writer wishes to urge those interested to a further study of the limits here graphically presented, with the idea either of confirming or improving them, because it is not profitable to resort to the very tedious processes incident to the methods presented by Mr. Gibson, except when a comparatively simple formula is inapplicable. The chart, Fig. 12, indicates that this is very rarely the case, and practically never need be, with proper care in the design and operation of any water system.

It is interesting to note that Mr. Gibson's methods may be used to work out a system of perfectly general cases, thus enlarging, indefinitely, the scope of such diagrams as he has presented, which are based, merely, on a specially selected set of data.

This is made possible by simply substituting in his scale of ordinates, values of the ratio $(h_{max.}) \div H$ in place of $(h_{max.})$, and substituting for the values of H, written on the curves, the values of K.

This trifling change, it will readily be seen, will make such diagrams applicable to an infinite variety of special cases.

In this manner, the chart, Fig. 13, has been roughly prepared, and, for the range of values covered, it is not necessary to resort to formulas. Mr. Johnson

All combinations of a, V, and H which produce a constant value of K must invariably result in a definite single value of the ratio

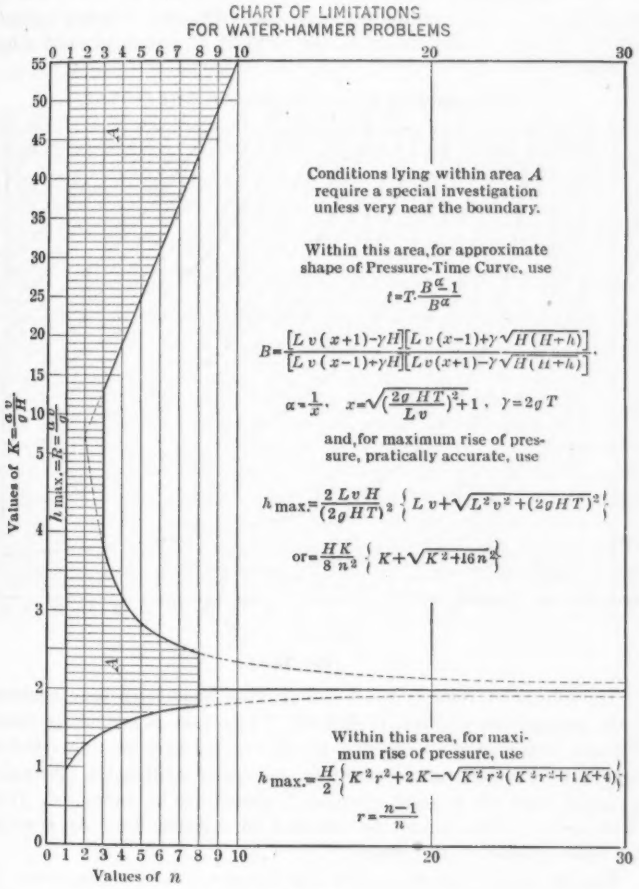

FIG. 12.

$(h_{max.}) \div H$ for each selected value of n. Therefore, in fact, each point of the chart covers, theoretically, an infinite variety of conditions.

Mr. Johnson.

In the use of the chart or simple formulas to replace the accurate but tedious methods, it should be borne in mind that it is not ordinarily practically necessary that the agreement should be perfect, because, as Mr. Gibson has shown, the shape of the curve is so sensitive to the vagaries of the gate motion, in closing, as to make it almost out of the question to reproduce, experimentally, any definitely selected shape of curve; so that, after all, the element of judgment must enter, as usual.

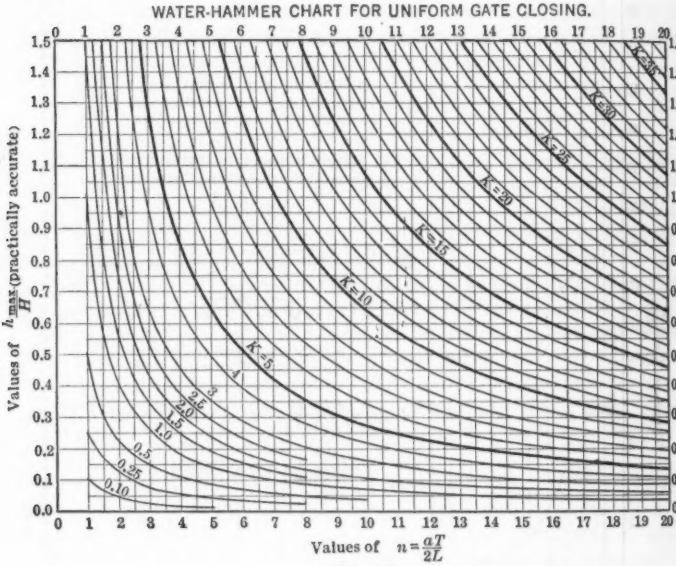

FIG. 13.

The effects of velocity head and friction head have been neglected in the preparation of Figs. 12 and 13. These factors are nearly always of minor importance, as affecting the rise of pressure, but, nevertheless, they may be taken into account by means of arithmetic integration in special cases where great accuracy is thought to be warranted. These effects, at any rate, cannot be included in a usable formula, covering the whole range of the charts.

For the benefit of those who are interested in the phenomena of water-hammer only sufficiently to desire a quick, comprehensive grasp of the derivation of the various formulas from fundamental principles, it seems worth while to present a simple analysis based on a straightforward hypothesis which has been generally accepted as applying

Mr. Johnson.

to elastic columns, but which has not, so far as the writer knows, been directly and clearly stated. This is attempted in the following language:

When a varying pressure is applied against the end of an elastic column, the change of velocity of that end, in the time required for the pressure wave to traverse the length of the column and return, is proportional to the arithmetic mean of the two pressures which there exist at the two extremities of this "interval" of time; and the impulse produced by the product of this average pressure and the time, $\frac{2L}{a}$, is equal to a change in momentum corresponding to the total mass of the column multiplied by the change in velocity of its end, adjacent to the point of application of the pressure.

This is a perfectly general statement applicable to any "interval," $\frac{2L}{a}$, of time during the acceleration (negative) of the elastic column.

If time is measured in "intervals" instead of seconds, we may write $\frac{2L}{a} \times n$ (intervals) $= t$ and $\frac{2L}{a} \times N = T$, where N is the total number of intervals (either a whole or mixed number) required to bring the end of the elastic column to a state of rest, and n, also either a whole or a mixed number, corresponding to any number of seconds, t.

With particular reference to a column of water arrested by the closure of a gate, we may designate the instantaneous pressures (h) above normal (H_0), at the extremities of any interval of time during closure of the gate, as h_{n-1} and h_n, respectively, and may write the general expression corresponding to the hypothesis (omitting the area of the pipe, assumed constant, and cancelling the common factor denoting the specific weight of the fluid), as follows:

$$\frac{h_{n-1} + h_n}{2} \times \frac{2L}{a} = \frac{L}{g}(V_{n-1} - V_n)$$

or, more simply,

$$h_{n-1} + h_n = \frac{a}{g}(V_{n-1} - V_n) \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

This is the simple relation of which Mr. Gibson took advantage in working out his arithmetic tables, and to which he refers at the end of the paragraph on page 719.

During the first interval, V_{n-1} becomes the initial velocity, V_0, and h_{n-1} becomes $h_0 = 0$, so, for values of n equal to or less than unity (or for values of $t \leqq \frac{2L}{a}$), we may write:

$$h_{n \leqq 1} = \frac{a}{g}(V_0 - V_n) \ldots\ldots\ldots\ldots\ldots\ldots (1A)$$

Mr. Johnson.

If the gate is completely closed in one interval or less, we have the maximum possible rise of pressure; for, in that case, V_n becomes zero and we may write:

$$h_{max.} = \frac{a}{g} V_0$$

which is the famous formula of Joukovsky.

Thus, it is clear how all these fundamental equations are derivable from the one general hypothesis which, itself, reverts to the second law of Newton.

Equation (1) comprises the essential features of the water-hammer problem for fast or slow-closing gates, and a particular case may be worked out for any known or assumed character of closure, with respect to time, by expressing the simple relation between the quantity of water discharging at any time through the gate-opening existing at that time, and the total pressure head which drives the water through it. For example, if ϕ_n represents the proportion, at any time, of full gate-opening, the area of which is b, and the coefficient of discharge is c, we have (neglecting heads due to velocity and friction),

$$\phi_n b c \sqrt{2 g (H_0 + h_n)} = A V_n \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

and

$$\phi_0 b c \sqrt{2 g (H_0 + h_0)} = A V_0 = b c \sqrt{2 g H_0} \quad \ldots\ldots\ldots (3)$$

where A is the area (constant) of the pipe.

Dividing Equation (2) by Equation (3),

$$\phi_n V_0 \sqrt{1 + \frac{h_n}{H_0}} = V_n$$

or, putting $\frac{h_n}{H_0} = P_n$, we have,

$$V_n = \phi_n V_0 \sqrt{1 + P_n} \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

and

$$V_{n-1} = \phi_{n-1} V_0 \sqrt{1 + P_{n-1}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

Subtracting Equation (4) from Equation (5),

$$V_{n-1} - V_n = V_0 \left(\phi_{n-1} \sqrt{1 + P_{n-1}} - \phi_n \sqrt{1 + P_n}\right) \ldots (6)$$

Thus, we have another expression proportional to ΔV, which may easily be made simultaneous with Equation (1), which latter may be rewritten, as follows:

$$V_{n-1} - V_n = \frac{g H_0}{a} (P_{n-1} + P_n) \quad \ldots\ldots\ldots\ldots\ldots (7)$$

Equating the second terms of Equations (6) and (7), we have the general water-hammer formula for closing gates, as follows:

$$P_{n-1} + P_n = K\left(\phi_{n-1} \sqrt{1 + P_{n-1}} - \phi_n \sqrt{1 + P_n}\right) \ldots\ldots (8)$$

where $K = \frac{a V_0}{g H_0}$.

The successive values of ϕ with respect to time are quite independent of the other factors of the equation, and they may be all

predetermined from an arbitrary or assumed character of gate closure, with respect to time. This may be expressed in the form of an independent curve plotted, for example, from some known motion of a particular gate with respect to time. Mr. Johnson.

If the gate closure is uniform, as Mr. Gibson has assumed in deriving his formulas, then the equation for ϕ may be written out, for subsequent use, or plotted as a straight line on a piece of cross-section paper. In this special case, the equation would be,

$$\phi_n = 1 - \frac{n}{N}, \text{ or } = 1 - \frac{t}{T}$$

as he states.

During the first interval, Equation (8) may be simplified to read,

$$P_{n \div 1} = K\,(1 - \phi_n \sqrt{1 + P_n}) \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

In order to "get a start" in computing the successive values of P, one interval apart, the first value of $\phi_{n \div 1}$ may be selected from the gate-opening curve at any convenient proportion of the first interval, and $P_{n \div 1}$ found from Equation (9).

Then, and thereafter, the successive values of ϕ taken from the curve, one interval apart, may be substituted in Equation (8) and the successive values of P_n found from the known values of P_{n-1} as the computations progress. If the complete pressure-time curve is desired, several different proportions of the first interval must be selected and the corresponding values of ϕ introduced first in Equation (9).

Equations (8) and (9) may be rearranged, of course, in the form of the solution of quadratics, separating out the values of P_n on one side, as Mr. Gibson has done, or these values may be solved by trial as he has done in making up his tables. The result is, naturally, the same in either case, and one method is no more nor less accurate than the other.

It is interesting to note the physical story told by a slight rearrangement of Equation (1) when $2h_{n-1}$ is subtracted from both sides. It then appears in this form:

$$h_n - h_{n-1} = \frac{a}{g}\,(V_{n-1} - V_n) - 2\,h_{n-1} \ldots\ldots\ldots\ldots (10)$$

Now, the term $\frac{a}{g}\,(V_{n-1} - V_n)$ represents the "natural rise" in pressure in a pipe of indefinite length, or at least so long that returning waves do not interfere with the natural rise during the time taken for the velocity to change the stated amount. This is the case in the first interval as shown by Equation (14).

We know from the principles laid down by Joukovsky that a supernormal pressure wave initiated at the beginning of any "interval" will become subnormal upon its return at the end of the "interval" of time,

Mr. Johnson.

or will be, so to speak, turned "upside down", and hence that its reducing effect on the pressure which would otherwise exist at the end of such "interval" is twice as great as the original supernormal value. This accounts for the term $2h_{n-1}$, and we may write another general hypothesis which is adequate for the statement of Equation (1), as follows:

The rise of pressure during any interval, $\frac{2L}{a}$, of time is equal to the "natural" or undisturbed rise, reduced by twice the value of the total pressure (above normal) which existed at the beginning of such "interval".

There are probably many ways in which to express the philosophy of Equation (1), and each may select the one best suited to his mind. The following is one of them:

If the pressure, h_{n-1}, should remain constant throughout the "interval" which it precedes, it is known, from the nature of an elastic column, that each and every particle of water would suffer the same diminution in velocity during the ensuing whole "interval" and, hence, that the change in velocity of the column, as a whole, would be faithfully recorded by the equal change at the end of the column, next to the gate. Call this portion of the velocity change, $\Delta_1 V$. Then, from the relation of impulse to change of momentum, we may write,

$$h_{n-1}\left(\frac{2L}{a}\right)=\left(\frac{L}{g}\right)\Delta_1 V, \text{ or, } 2h_{n-1}=\left(\frac{a}{g}\right)\Delta_1 V$$

Now, any pressure added later in the interval under consideration, could have time, during such interval, to distort only a portion of the water column (of total round-trip length, $2L$), and the change in velocity produced at the end of the column by any such increment of pressure, Δh, may be derived as follows:

The mass affected in the time, dt, is proportional to adt.

This mass, multiplied by its acceleration, equals the increment of force to produce the acceleration. Therefore,

$$dh=\left(\frac{a}{g}\right)dt\times\left(\frac{dv}{dt}\right), \text{ or, } \Delta h=\left(\frac{a}{g}\right)\Delta V$$

Calling this additional change in velocity (of the end of the column), $\Delta_2 V$, we may write:

$$\Delta h=\left(\frac{a}{g}\right)\Delta_2 V$$

but,

$$V_{n-1}-V_n=\Delta_1 V+\Delta_2 V, \text{ and, } \Delta h=h_n-h_{n-1}$$

Hence,

$$2h_{n-1}+h_n-h_{n-1}=h_n+h_{n-1}=\left(\frac{a}{g}\right)(V_{n-1}-V_n)$$

MINTON M. WARREN,* ASSOC. M. AM. SOC. C. E. (by letter).—This paper goes into the mathematical theory of ordinary water-hammer more thoroughly than any previous discussion of the question, and is certainly a valuable addition to the literature on this subject. The curves presented by the author show the differences in the various formulas with great clearness. Mr. Warren.

The writer, however, does not believe that Mr. Gibson's method and formulas are practical for ordinary use for three reasons:

First.—In order to use the formula, a large amount of very tedious figuring must be done, and unless it is very carefully checked by logarithms, a very small arithmetical mistake may make a large error in the result.

Second.—The formulas have not been confirmed by experiments and are based on certain assumptions the accuracy of which are open to question.

Third.—In most cases, simpler formulas will give as accurate results as the data warrant.

It is almost impossible to get away from the idea that the more calculations and exact mathematical methods used in obtaining a result in engineering, the more accurate the result will be, regardless of the assumptions on which the calculation is based. It is the same false accuracy that leads engineers to submit cost estimates figured down to odd cents on projects running into millions.

The writer does not believe that the many assumptions needed in deducing any formula for slow-closing gates warrant the elaborate methods used by Mr. Gibson, until these methods and formulas are backed up by careful and extensive experimental data, as were the formulas of Professor Joukovsky.

In arriving at his results, Mr. Gibson assumes that the area of the gate is closed at a uniform rate, whereas the writer, in deducing his simple formula,

$$h = \frac{L\,V}{g\left(T - \frac{L}{a}\right)}$$

assumed that the gate moved in such a way as to cause the pressure to rise at a constant rate. In any given case, neither assumption is strictly true, and experiment alone will show which is nearer the average gate motion.

Referring to Fig. 9, it is seen that, according to the author's calculations, such a gate motion, giving a constant rise of pressure, is not far from a straight line, and probably as near the truth in ordinary

* Boston, Mass.

Mr. Warren.

gates as his assumption (uniform reduction of area), which makes the mathematics very much more difficult.

There is great need for a series of careful experiments on slow-closing gates, and it is to be hoped that Mr. Gibson, or some other member of the Society, will undertake this work. Data from such tests properly used would be of more service to the Profession than the most perfect theoretical formulas which have never been tested. Until this is done, engineers will have to base design on the meager practical data available, guiding their judgment by unproved formulas, and the writer has found that the simple formula given above comes nearer the pressures he has observed in practice than other formulas, although, like the others, it is based on certain assumptions which are not strictly true.

In recent tests by one of the best-known manufacturers of water-wheel governors, the author's formula has given results so closely in accord with the tests, that it has been adopted for general use. As this company has many chances to obtain practical operating values of water-hammer, its conclusions are certainly of interest, in default of other experimental data.

In regard to Mr. Halmos' statement that this formula can never give true results, even accidentally, it should be noted that, under certain conditions, it gives the same results as the formula which he uses (Allievi's), and, in some of the tests mentioned in the previous paragraph, has given results within the probable error of the pressure gauges used.

In one point, Mr. Gibson's formula gives what appears to the writer unreasonable results. This is illustrated in Fig. 4, where the curve rises very sharply between heads of from 10 to 100 ft. Alliévi's curve rises even more sharply and can be easily proved wrong, as it reaches values of h which are far above the maximum value possibly reached in instantaneous closing.

Mr. Gibson's curve stops at that value, but the writer does not believe that experiments confirm the large increase in water-hammer for low heads over that for high heads. His assumption that the waves are perfectly reflected from the slowly closing gate is also open to question, and was not proved in Joukovsky's experiments.

It is not intended to imply that Mr. Gibson's formulas may not prove to be as accurate or even more accurate than the others, but, in the absence of any experimental proof, their added complexity does not seem to be warranted, in view of the approximations and assumptions on which they are based.

Mr. Anderson.

J. T. Noble Anderson,* M. Am. Soc. C. E. (by letter).—On several occasions, the writer has investigated this question, or a cognate phe-

* Narbethong, Victoria, Australia.

nomenon, with pumps—centrifugal and others—through long pipes. In one case, there were two pipes with a common penstock—each of wood, 3 ft. in diameter, and 2 300 feet long. In every case, he has been greatly impressed by the extreme complexity of the subject. Mr. Anderson.

With the help of Professor Joukovsky's theory and some "rule-of-thumb" guesses, gained from a general experience, these pipe lines and the values concerned can now be calculated to as close an economic margin as most other engineering problems. At the same time, the result of experience shows so many baffling discrepancies, that the experimental results, which the author hopes to obtain "in the not too distant future", will be waited for eagerly.

The care he has taken to collect and co-ordinate the formulas, is an earnest that he may be relied on to record fairly and fully not only his results, but all the extraneous facts and happenings which may, however remotely, bear on the many irregularities between actual records and what the formulas anticipate. In particular, it might help if two slightly disturbing factors were recorded in each test, that is: (1) the temperature of the water, and (2) the proportion of free air present in the water.

The second factor will probably be quite immaterial, but, in a case where the substance pumped through a centrifugal was sewage with a specific gravity of 64 lb. per cu. ft., the writer found that the gases contained had a very disturbing influence.

In some recent investigations, the writer used a steam indicator with springs specially chosen for the anticipated pressure. Some indication of the author's apparatus will no doubt be given.

Ford Kurtz,* Esq.† (by letter).—Mr. Gibson has made a valuable addition to the too few and scanty English treatises on the mathematical theory of water-hammer. His treatment of the subject, however, is chiefly of value in obtaining, without the use of differential equations and from physical laws the import of which is readily grasped, formulas which give the same practical results as the much simpler and less cumbersome equations of Lorenzo Alliévi, first published in Rome, in 1903. These equations must not be confused with the confessedly approximate and inadequate formula designated by Mr. Gibson as the "Alliévi formula", and on which Mr. R. D. Johnson has apparently founded a pressure-time equation. The equations referred to are mathematically rigid formulas which take into account not only the effect of net head but also the compressibility of the water and the extensibility of the pipe and which, as far as the writer knows, have never before been published in English. In 1911, the writer prepared, for his own use, a translation of a German translation of Mr. Alliévi's Mr. Kurtz.

* New York City.

† Now M. Am. Soc. C. E.

Mr. Kurtz.

work, and found the latter's treatment so remarkably comprehensive and thorough that he has used it ever since in all water-hammer problems. The German translation* can be found in the Engineering Societies Library.

In presenting the exact formulas of Alliévi, the following nomenclature will be added to that of Mr. Gibson's paper:

$R_0 = \dfrac{a\,V_0}{g}$ = excess, or water-hammer, head due to instantaneous complete closure of gate.

$m = \dfrac{a\,V_0}{g\,H_0}$ = ratio of instantaneous water-hammer head to net head.

$F(t)$ and $f(t)$, or simply F and f = certain functions of time, t.

$z = \dfrac{H_0 + h_t}{H_0}$ = ratio of total variable head to net head.

$\phi(t)$ = gate-opening at time, t, as a ratio of maximum gate-opening.

The exact formulas of Alliévi contain a term which makes it possible to determine the pressure at any point of the pipe line at any moment, but the writer is presenting only the simple form for determining pressure at the outlet, or discharge section just up stream from the gate, as that is the problem investigated by Mr. Gibson. It is also assumed that the pipe line is of uniform thickness and diameter throughout its length. Then, during the period,

$$0 < t \leqq \frac{2\,L}{a},$$

$$z = 1 + \frac{F(t)}{H_0},$$

where

$$\frac{F(t)}{H_0} = m + \frac{m^2}{2}[\phi(t)]^2 - m\,\phi(t)\sqrt{1 + m + \frac{m^2}{4}[\phi(t)]^2}$$

and, during the period,

$$\frac{2\,L}{a} < t \leqq T,$$

$$z = 1 + \frac{F(t)}{H_0} - \frac{F\left(t - \dfrac{2\,L}{a}\right)}{H_0} = 1 + \frac{F(t)}{H_0} - \frac{f(t)}{H_0},$$

* "Allgemeine Theorie über die veränderliche Bewegung des Wassers in Leitungen," von Lorenzo Alliévi, 1909.

Mr. Kurtz.

where

$$\frac{F(t)}{H_0} = m - \frac{f(t)}{H_0} + \frac{m^2}{2}[\phi(t)]^2 - m\,\phi(t)\sqrt{1 + m - \frac{2\,f(t)}{H_0} + \frac{m^2}{4}[\phi(t)]^2}$$

For the linear law of gate movement, $\phi(t) = 1 - \frac{t}{T}$, as already stated by Mr. Gibson.

These formulas applied to Mr. Gibson's first example give the following equations:

For $$O < t \leq 0.35 \text{ sec.},$$

$$\frac{F(t)}{H_0} = 10.35008 + 53.56185\,\phi^2 - 10.35008\sqrt{11.35008\,\phi^2 + 26.78092\,\phi^4}$$

and, for $$0.35 < t \leq 6.0 \text{ sec.},$$

$$\frac{F(t)}{H_0} = 10.35008 - \frac{f(t)}{H_0} + 53.56185\,\phi^2 - 10.35008\sqrt{\left(11.35008 - \frac{2\,f(t)}{H_0}\right)\phi^2 + 26.78092\,\phi^4}$$

As already noted by Mr. Gibson, the values of $\frac{F(t)}{H_0}$ and $\frac{f(t)}{H_0}$ are so small compared with some of the individual terms of the equations, that it is necessary to use logarithms in solving the equations.

Using the exact Alliévi equations as given previously, Table 6 has been prepared, showing the rise of pressure and also the differences between the values of the rise obtained by Alliévi equations and those obtained by Mr. Gibson's equations. The maximum divergence of less than one-half of 1% shows the remarkable agreement of the two methods. It is apparent, however, that the simplicity of the solution by the Alliévi formulas, without giving heed to magnitude and direction of waves in the computations, makes it far superior to that of Mr. Gibson as a working method.

The exact formulas of Alliévi also furnish equations similar to those given previously for the case of the opening of a valve at the lower end of a pipe line, either from fully closed position, or from some initial partial opening. As already stated, in their complete form they also give the pressure at any time for any point along the pipe line, thus covering the matter mentioned by Mr. Gibson as to be discussed by O. V. Kruse, Assoc. M. Am. Soc. C. E. Of course, there are also exact equations for the velocity at any time for any point along the pipe line.

Mr. Kurtz.

The partial differential equations for the general motion of water in pipes are based on the fundamental differential formulas for the motion of water in general. Unfortunately, these partial differential equations, four in number, cannot be integrated (not even by approximate arithmetic integration so far as the writer knows) without making the following simplifying approximations:

1. Velocity in direction of axis of pipe considered uniform over any chosen section of the stream.

2. Skin friction and viscosity neglected.

3. Velocities at right angles to the axis of the pipe, due to expansion or contraction of the pipe by changes in pressure, neglected.

4. Pressure considered uniform over any chosen section of the stream.

5. Assumed that the pipe consists of individual circular elements independent of each other, which are freely extensible.

6. Assumed that the ratio of velocity of water in the pipe to the velocity of propagation of pressure changes is small enough, compared with unity, so that its addition thereto or subtraction therefrom can be neglected in every case at every instant.

By making these approximations, we obtain the so-called exact formulas of Alliévi.

Mr. Gibson's method of taking account of skin friction (which is only approximate, as has been pointed out by William P. Creager, M. Am. Soc. C. E.) could easily be applied to the exact Alliévi formulas by changing the factor m so as to have it correspond at all times to $(H_0 + h_f)$ instead of to H_0. The exact Alliévi formulas can be applied so as to take account of varying diameters and thicknesses of pipe in the same line, but they soon lead to so much complication that they become impracticable. In such cases, the writer uses the formulas as already given for a pipe of uniform diameter and thickness, but gives to m the value, $\dfrac{Q_0 \Sigma \dfrac{L}{A}}{g\, H_0 \Sigma \dfrac{L}{a}}$, where Q_0 equals the flow of water in a pipe at full gate-opening, L equals the length of any section of pipe, A, its cross-sectional area, and a, its individual value of the velocity of propagation of pressure changes. Also, the factor, $\dfrac{2\,L}{a}$, must everywhere be changed to read $2 \Sigma \dfrac{L}{a}$. This is confessedly an approximation made without mathematical proof, but it is probably exact enough for practical purposes in the majority of problems.

Mr. Creager.

WILLIAM P. CREAGER,* M. AM. SOC. C. E. (by letter).—The theory of water-hammer in penstocks is one of the most intricate problems confronting engineers. Mr. Gibson has made a considerable addition to the knowledge of the subject; but exact solutions for all conditions have not yet been reached.

The author has developed rational equations for penstocks of constant diameter and negligible friction head. In cases where friction head is relatively large, and particularly where the penstock has a varying diameter, we are still very far from a practical solution.

At any instant during gate closure, the discharge through the gate is a function of the static head plus water-hammer head less friction head, all measured at the gate.

On page 725, the author makes the assumption that the friction head at the gate is proportional to the square of the velocity adjacent to the gate. This assumption appears to the writer to be only approximate, since it is well known that, at any instant during surges, the velocity is materially different at different points on the penstock.

* New York City.

Mr. Creager.

It is the writer's opinion that, during the period, $\frac{2L}{a}$, subsequent to a single small instantaneous closure, the friction head at the gate is not constant, although the velocity adjacent to the gate during that period is constant. This constantly varying friction head makes it very difficult to include this feature in the equations for water-hammer and, in all probability, the author's methods are as close as can be obtained. It would be of interest to know how much difference the inclusion of friction head makes in ordinary problems.

For a penstock with varying diameter, auxiliary waves are set up each time a water-hammer wave passes a point of change in diameter. For this condition, the author's equations would not apply. His methods would apply, but they would be exceedingly difficult, if not impossible, of practical application.

It is evident that the maximum rise of pressure is materially influenced by the characteristics of the gate-closure curve. It is well known that modern turbine governors do not provide a uniform rate of gate closure throughout the stroke. It is also possible that governors of different types have different closure characteristics. Consequently, complete data for the determination of maximum water-hammer for specific cases must include the gate-closure characteristics of the governor which is to be a part of the machinery.

Mr. Gibson.

NORMAN R. GIBSON,* M. AM. SOC. C. E. (by letter).—In closing the discussion of his paper, the writer desires, first of all, to make amends, as far as possible, for the injustice unknowingly done to Mr. L. Allievi by the reference to his formula on the diagrams and in the text of the paper. As pointed out by Mr. Halmos, the formula designated by the writer as Allievi's is only one of several contained in his complete work. While "ignorance excuseth none", the writer can only plead, in extenuation, that he did not read Allievi's work, because he could not find an English translation of it, but was led to believe, by the frequent references to "Allievi's formula" in English literature on the subject, that the formula quoted was, in fact, the one and only equation derived by Allievi. The writer was the more completely led astray by a lengthy reference to this formula in a paper published in the *Transactions* of the Society, from which it could not but be inferred that the author had read the work of Allievi in the original language. It is inconceivable how any one, having read it, could so overlook the most important part of Allievi's work.

The writer is indebted to Mr. Halmos and Mr. Kurtz for having brought to light some further formulas of Allievi, as published in the German and Italian languages. Mr. Halmos states that the writer's solution agrees in every particular with that of Allievi, and Mr. Kurtz finds a close agreement in an arithmetical example.

* Niagara Falls, N. Y.

Mr. Gibson.

The identity of the results obtained by the Allievi equations with those derived from the writer's may be proved as follows:

Considering first Equation (3) presented by Mr. Halmos on page 750, it should be noted that Mr. Halmos had the writer's attention drawn to a mistake in his definition of $\psi(t)$. This symbol stands for the ratio of the instantaneous area of discharge to the area of the pipe (not the area of the gate-opening at the time, $t = 0$).

The two nomenclatures are as follows:

Halmos.	Gibson.
$\psi(t) = \left(1 - \frac{t_n}{T}\right) \frac{B_0}{\sqrt{2g}}$	$= \sqrt{\frac{S_{t_n}\, g}{2\, a^2}}$
$y_0 = H_0$	
$y = H_0 + h_{t_n}$	
$H = H_0 + \frac{a\, V_0}{g}$	
$c_0 = V_0$	
$C = V$	

On page 750, Mr. Halmos states that $F(t)$, found in the first interval, should be substituted for (f) in Equation (3), in order to obtain the value of y for every subdivision of the second interval.

Using the subscript n of the writer's notation, the relation between $F(t)$ and (f), may be expressed by the equation:

$$f(t_n) = F(t_{n-1})$$

Again, on page 750, Mr. Halmos gives:

$$F(t) = \frac{a}{g}(c_0 - C) - f$$

Substituting the subscript, n, and the writer's notation for c_0 and C,

$$F(t_n) + f(t_n) = \frac{a}{g}(V_0 - V_{t_n})$$

$$\therefore 2\frac{a}{g}(V_0 - V_{t_n}) = 2\{F(t_n) + F(t_{n-1})\} \quad \ldots\ldots\ldots (1)$$

and, similarly,

$$2\frac{a}{g}(V_0 - V_{t_{n-1}}) = 2\{F(t_{n-1}) + F(t_{n-2})\} \quad \ldots\ldots\ldots (2)$$

Subtracting Equation (1) from Equation (2):

$$2\frac{a}{g}(V_{t_n} - V_{t_{n-1}}) = 2\{F(t_{n-2}) - F(t_n)\}$$

If each term in the writer's general expression for R is now expanded in terms of V, then:

$$R_{t_n} = R_0 + 2\frac{a}{g}\{(V_{t_n} - V_{t_{n-1}}) + (V_{t_{n-2}} - V_{t_{n-3}}) + \ldots\ldots\ldots\ldots\}$$

Mr. Gibson.

and, by analogy:

$$R_{t_n} = R_0 + 2\left[\tfrac{1}{1}F(t_{n-2}) - F(t_n)\tfrac{1}{1} + \tfrac{1}{1}F(t_{n-4}) - F(t_{n-2})\tfrac{1}{1} + \ldots\ldots\right]$$

and, by cancellation:

$$R_{t_n} = R_0 - 2F(t_n)$$

and

$$R_{t_{n-1}} = R_0 - 2f(t_n)$$

By substitution of the above values and by reference to the relation of terms in the paper, Allievi's Equation (3), as given by Mr. Halmos on page 750, may be written for any interval, n:

$$(H_0 + h_{t_n})^2 - 2(H_0 + h_{t_n})\left(H_0 + R_{t_{n-1}} + \frac{S_{t_n}}{2}\right) + \tfrac{1}{1}H_0 + R_{t_{n-1}}\tfrac{1}{1}^2 = 0$$

and by solving this quadratic:

$$h_{t_n} = \frac{1}{2}\tfrac{1}{1}(S_{t_n} + 2R_{t_{n-1}}) \pm \sqrt{St_n(St_n + 4R_{t_{n-1}} + 4H_0)}\tfrac{1}{1} \ldots\ldots(3)$$

which is the writer's general expression, similar to Equation (10) on page 724, for h at any time in any interval.

Mr. Kurtz has presented the general Allievi formula in somewhat different form from that used by Mr. Halmos, in that the values of V and h at the interval points, as contained in the writer's values of R, are eliminated, and the labor of computation is thereby reduced. The writer's equations, however, require no more heed to be given to "magnitude and direction of waves in the computations" than do the Allievi equations. Mr. Kurtz's remark in this connection, on page 767, probably refers to the explanation of the work of arithmetic integration which preceded the writer's derivation of his formulas. Mr. Kurtz's Table 6 of arithmetic errors indicates merely the difference in the results that might be obtained by two computers. The results given by the Allievi formulas are identical with those of the writer.

The elimination from the writer's equations of V and h at the interval points may be accomplished in the following manner: Referring to the equations on page 724, the expression for R_{t_1} may be equated to that part of the equation remaining after R_{t_1} has been substituted in place of $\frac{a}{g}V_1 + h_1 - C_{t_1}$.

Thus, in general,

$$R_{t_{n-1}} = \frac{a}{g}\left(1 - \frac{t_n}{T}\right)B_0\sqrt{H_0 + h_{t_n}} + h_{t_n} = \frac{a}{g}V_{t_n} + h_{t_n}$$

$$= \frac{a}{g}V_n + \frac{a}{g}(V_n - V_{t_n}) + h_{n-1} - C_{t_{n-1}} = \frac{a}{g}V_{t_{n-1}} - h_{t_{n-1}}$$

$$= \frac{a}{g}\left(1 - \frac{t_{n-1}}{T}\right)B_0\sqrt{H_0 + h_{t_{n-1}}} - h_{t_{n-1}}$$

$$\sqrt{S_{t_{n-1}}(H_0 - h_{t_{n-1}})} - h_{t_{n-1}} \ldots\ldots\ldots\ldots(4)$$

If this value of $R_{t_{n-1}}$ is substituted in the writer's equations in place of the value given in the nomenclature on page 722, the labor of solving problems by the formulas will be lessened. Mr. Gibson.

Mr. Johnson's discussion contains considerable new matter which will be found most helpful in solving problems of the kind under consideration. His remarkably simple and concise presentation of the fundamental principles of this subject and his derivation of the expression for $\frac{h_n}{H_0}$, the ratio at any time of the rise of pressure to the net head, are particularly noteworthy and important. His chart of limitations, shown in Fig. 12, makes it possible to see at a glance where it is safe to apply the general logarithmic curve given by Allievi's Formula (4), which is Mr. Johnson's Equation (7), and also to see where the maximum pressure rise occurs at the end of the first interval. As pointed out by Mr. Johnson, his Equation (7) covers a wide range of conditions, and it will be found convenient to use this equation wherever it applies. In Fig. 13, Mr. Johnson has indicated how an exceedingly useful chart may be prepared by resorting to the expedient of solving for the ratio, $\frac{h_{max.}}{H_0}$, instead of for $h_{max.}$ directly. Such a chart may be made to show graphically a range of results as wide as desired and, as stated in the discussion, each point on the chart covers an infinite number of cases.

Mr. Creager's desire to know more about the application of water-hammer formulas to pipes of varying diameter will be appreciated by every one who studies this subject. Needless to say the problem is a complex one, but it seems certain that the fundamental relations that have been developed herein can be applied not only to this but to any water-hammer problem. The point brought out by Mr. Creager that the friction head at the gate is not constant during the period of $\frac{L}{a}$ is worthy of consideration, but the writer would suggest that the change in friction head, being a change in pressure, cannot traverse the length of the pipe at a rate faster than the velocity, a. In any event, even though the friction head does vary during the interval periods, it would seem that the net result throughout the closing time would be that the friction and velocity heads are recovered proportionately to the rate at which the velocity of flow is destroyed.

On page 769, Mr. Creager misquotes the assumption made on page 725 of the paper. The friction head at the gate was assumed to be proportional to the square of the velocity of flow, not the velocity "adjacent to the gate."

During the past year many experiments on pressure rise have been made by the writer with specially designed apparatus. Most of the ex-

Mr. Gibson.

periments, however, were made in connection with his new process for the measurement of the flow of fluids in closed conduits, and as this work continued until late autumn, it has been necessary to postpone until later the particular experiments that have been proposed to show the relation between gate motion and pressure rise covered by the formulas. As soon as possible the results of these experiments will be made available for publication, and in assembling the data Mr. Anderson's request for full particulars will be remembered.

In reply to the criticism of Mr. Warren, it may be observed at once that the vital importance of including the initial static head among the factors that determine the maximum rise of pressure, cannot be considered in the same class as "odd cents in million dollar estimates". The large increase in water-hammer for low heads over that for high heads when the gate motion is uniform, is caused by the influence of the initial head.

Mr. Warren cannot obscure the points at issue by clouding the discussion with conjectures as to whether uniform gate motion or the gate motion he has assumed, but not defined, "is nearer the average gate motion". The vagaries of gate motions are not under consideration, as is clearly stated on page 710. The problem considered is the rise of pressure following any given gate closure, and, for this purpose, in deriving the formulas, uniform gate motion has been assumed. Diagrams of non-uniform gate motion were shown and attention was drawn to the effect of such non-uniform motion on the shape of the pressure-time diagram. In all practical cases, actual conditions will be determined and, as Mr. Johnson says, "the element of judgment must enter as usual". Mr. Warren's statement that his formula is based on a certain prescribed shape of the pressure-time diagram which may be produced by a special, though undescribed, performance of the gate, condemns his formula for general use, because it is impossible to adapt it to any particular gate motion. Indeed, what he says of his own arbitrary diagram is equally true of any form whatever which gives a value of the maximum pressure rise greater than the mean effective pressure rise and which encloses a proper impulse area.

For uniform closure, Mr. Warren's formula always leads to errors on the wrong side, that is, it gives less than the true value. In the region, pointed out in the paper, where it is approximately correct, and when the first interval is a small proportion of the closing time, as it frequently is in ordinary cases, this formula gives a result close to the value of the mean rise of pressure which can be determined by the simple expression, $\frac{L\,V}{g\,T}$.

Mr. Warren questions the assumption that pressure waves are perfectly reflected from the slowly closing gate. The question implies a

misconception of the nature of the waves themselves. They are not of a substance that rebounds like a rubber ball, but are conditions of the water column at various times at different points along the pipe line. When a wave is started by a movement of the gate, the water is put into a state of super-normal pressure and it remains in this condition at the gate until the wave has traversed the length of the pipe to the origin and back again. When the wave has returned to the gate, the state of super-normal pressure there is converted to one of sub-normal pressure and the water there remains in this condition until the wave has again traversed the distance to the origin and back, whereupon the condition at the gate again changes to a state of super-normal pressure, and so on. At points along the pipe the changes of condition occur in the same sequence, except that a state of normal pressure exists for a time between the periods of super-normal and sub-normal pressures. When the gate is gradually closing, the algebraic sum of the innumerable infinitesimal waves (super-normal pressure being considered positive and sub-normal pressure negative) fixes the pressure that exists at the gate at any time during the closure. Mr. Gibson.

The authority for the assumption that the flow of water in the pipe does not affect the wave is to be found on page 709 in the following quotation from Miss Simin's translation of Joukovsky's work:

"If the water column continues flowing, such flow exerts no noticeable influence upon the shock pressure. In a pipe from which water is flowing, the pressure wave is reflected from the open end of the pipe, in the same way as from a reservoir with constant pressure."

Finally, it may be stated definitely that, as an empirical rule for convenient use, Mr. Warren's formula is quite untrustworthy, and as an equation showing the relation between velocity destroyed and rise of pressure, it is fundamentally and inherently wrong.

Paper No. 1440

ADDRESS AT THE ANNUAL CONVENTION IN ST. PAUL AND MINNEAPOLIS, MINN., JUNE 17TH, 1919.

By Fayette S. Curtis, President, Am. Soc. C. E.

For the last two years the Annual Convention of the Society has been omitted on account of the war; therefore, the Presidential Address has been delivered at the Annual Meeting in January. The fact that we are again in a position to resume our Convention meetings is, I am sure, a source of unbounded gratification to all.

In this address I ask pardon if I digress somewhat from the trend of former addresses and speak of the fundamental principles of the engineer, his duties, what he has accomplished and can accomplish in the future, the application required to make work successful, and the distinction that may be gained through uprightness and honest labor.

It is quite probable that some of you have often been asked the question: "Do you recommend Civil Engineering as a profession?" and I assume that generally an affirmative answer has been given. The civil engineer, when thoroughly fitted for his profession, immediately becomes useful to society and the world of materiality. He is prompted by the wants of society, and is constantly originating other wants by the improvements he introduces. He is also creative, and his profession is not mortgaged to power or influence, but stands firmly on its own foundation—encouraged by world-wide influences.

His duty consists in designing, arranging, and building structures or machines which require the immediate superintendence of those who are acquainted with not only the principles but the practice of con-

struction; for engineering is a branch of knowledge that takes its place both among the Sciences and the Arts.

Therefore, to be eminent in his profession, or any branch of it, he should be able, not only to design and plan, but to supervise construction. Those who have only the knowledge of how to design and plan, and are unable to execute, become confused in meeting the many contingencies which arise.

The profession, embracing as it does almost every kind of construction, requires a very extensive and general acquaintance with other sciences, in order that the engineer may be qualified to accomplish successfully the various works on which he may be engaged, and to overcome those difficulties which frequently arise unexpectedly in the progress of his work, and, but for that knowledge and talent, threaten its final success.

Thomas Telford, in his "Descriptive Narrative of his Professional Labours", has said:

"How can a man give judicious directions unless he possesses personal knowledge of the details requisite to effect his ultimate purpose in the best and cheapest manner? It has happened to me more than once, when taking opportunities of being useful to a young man of merit, that I have experienced opposition in taking him from his books and drawings, and placing a mallet, chisel or trowel in his hand, till, rendered confident by the solid knowledge which experience only can bestow, he was qualified to insist on the due performance of workmanship, and to judge of merit in the lower as well as the higher departments of a profession in which no kind or degree of practical knowledge is superfluous. For this reason I ever congratulate myself upon the circumstances which compelled me to begin by working with my own hands, and thus to acquire early experience of the habits and feelings of workmen; it being equally important to the Civil Engineer, as to Naval or Military Commanders, to have passed through all the grades of their profession."

It is no doubt true that many men have gained prominence in their profession by individual effort—practicing and studying at the same time, with a view to acquiring a full knowledge of all necessary scientific principles. Students are required to spend a certain time in acquiring technical knowledge, but must not then think they are

engineers in the broad meaning of the term, capable of constructing and being responsible for engineering work, as that is a false idea.

No one can doubt that the addition of the natural sciences to the old-time arts course has greatly enriched it, and the sciences are now undoubtedly the most important part of a liberal education; but there is another side, which we cannot ignore, and that is, that after all, the great object of a good education is not so much the accumulation of knowledge as the development of mental power in the individual.

The tendency toward scientific and practical education is no new thing. Men have come to see that the first mental training can be made more effective by solving physical problems than by studying the dead languages, because as much true value can be obtained in the study of Nature as in the study of man's conception of Nature. First knowledge is more satisfactory to the best of minds.

The profession has become so diversified that after having secured a good fundamental training it would be worth serious consideration to take up a single branch of engineering practice, as it can hardly be expected that the civil engineer will become proficient in every branch. He would be better able to give his best endeavors to attaining the highest proficiency in some particular line, and, at the same time, grasp or understand in a general way the subjects which may relate to the several kinds of works, as the whole subject is so broad that it would be vain to attempt to understand them all in all their details.

Ambition to obtain as great a knowledge as possible is to be admired and encouraged, but to attain the highest standard in one branch is more commendable than to attempt to reach special eminence in all, as the student will be apt to find himself oppressed with a weight which he is not capable of sustaining, and this will be very likely to result in utter failure.

The professional man should not make the mistake of thinking that he can reach the top in an unconcerned and idle manner, believing that by some easy process he will reach and hold it. The structure on which he stands must be constructed by piece and parcel, every member thoroughly tested by a gradual and difficult process; he must experience all the difficulties, trials, and troubles to be met on the way, in order to support and sustain him at the higher elevation to which he aspires. To such the doors to success are open. Work seeks the best hands, as naturally as water runs down hill, but seldom seeks one whose only recommendation is that he needs it. If he is not willing

to go slowly through the maturing process of time, through patient work, by steady application step by step preparing himself for the work ahead, which has made men prominent and efficient in their profession, then, alas, the result is doubtful. It is like the student who prepares his education for future advancement. He goes from grade to grade until he is master of the science on which he has to build, taking no upward step until the last has been tested and found not wanting in any characteristic which will sustain him and serve him to build on for the future.

New problems are all the time arising. The tremendous growth of our complex industrialism means the facing of new conditions, that we may overcome new difficulties and enjoy new benefits. Therefore, there is only work to face, and it should be met with a spirit characteristic of the creator of science, and thereby much may be accomplished.

There is no success without hard and earnest labor. Never balk at a few obstacles, but hang on with all your might; this, in the end, will give success. It is true that many experiments will have to be made, but there can be no doubt of ultimate success if our aim is a determination to succeed and we do not become discouraged.

As we look back, even over a short time, how often have we said to ourselves, after completing some important structure, "This should last for many years—we have reached the limit;" but within a comparatively brief period have we not seen that structure replaced by another, larger and more expensive, which has been demanded by the growth of business? We have not stopped building, nor have we come to the time when we have built sufficiently for the future, and we never will, as long as the richness of this country is undeveloped and its physical and financial growth continues. To stop this great advancement, which the people continue to make, would be death. Then, does it look as though there was not a future for the engineer who has integrity and perseverance, as he is and must be the practical foundation or basis for all which we are to build, in order to accomplish a higher and nobler position in society?

The work of the engineer is the foundation on which rests the growth of this great Republic, not only physically but financially. He is one of the prime factors, and could not by any possibility be dispensed with. We are not an organization which threatens to pull

down and wreck or destroy what we have built, but an educational organization, and hope to get the necessary recognition of our rights through education. No doubt the engineer has often had his line of procedure curtailed by some power having authority to suspend or discharge at will, at the pleasure of some controlling power, ignorant, and with no understanding of the conditions or the difficulties the engineer may have to meet, and without the least knowledge of engineering subjects.

Civil engineering is ages old, but has always shown a steady progression, possibly not as to more substantial work, but certainly in the facilities provided in machinery to do its work. As to its beginning, I will not undertake to say, but will only refer back to those times of which we may have knowledge, and ask if the great work done is not a credit to the scientific ability of this profession? But what is the future to be? Does it depend on those who are coming into this Society —educated, experienced—to show to the world that they can and will continue to build and improve the financial and social conditions? For a determination we must wait on time.

Is the engineer being benefited by his connection with this Society? It has been said that the Society is becoming less democratic and more conventional, or, in other words, is not taking sufficient interest in, or having proper regard for, its members, and, therefore, they are without the opportunities or advantages which they might gain in local societies. This Society has grown to such an extent that contact personally with all its members is not possible, but the interest and devotion and brotherly love of its members are just as great as ever. The information in the different papers by the most prominent engineers of the country, presented and distributed, is of the greatest importance to the members of the Society. As the Society grows, this information increases, and the papers are more numerous and contain information and knowledge which cannot be obtained except through the parent society. If not, why are so many engineers anxious to affiliate themselves with this Society? They know it gives them prestige the world over, and sets a standard which has been passed upon and approved by the highest of professional men. Our Constitution requires that standard to be higher than that of any of the local societies.

The Society has not only grown in numbers, the increase within the last ten years being 85%, but has increased in influence in the estimation of the public and the world at large; our members are looked up to as the leaders in the Engineering Profession. Then, who can say that it, as an engineering society, has depreciated, gone back, or fallen off one iota from its former standing? On the contrary, it has grown steadily stronger and stronger. Its members have become of such strength, in the material and financial upbuilding of the Government, that they are indispensable.

Therefore, we must not permit ourselves to forget the obligation we owe to the founders of this Society, the men who gave their time and talent in creating an organization which has proved to be of untold benefit to the Engineering Profession. How, then, are we to repay them, if not by giving to the Society our support and assistance, promoting good fellowship among its members, encouraging its officers, and giving a helping hand to the future engineer who comes into the Society, passes up through the different grades of experience, and is seeking information? Let us all do something in the interest of the Society, and thereby broaden its influence and add to its high standards of proficiency.

We certainly cannot help by creating dissensions among the members, or becoming dissatisfied with the earnest labors of those whom we select to bear its responsibilities, or in getting the idea that we are connected with this Society wholly for what we can get out of it. No matter how much we give, we can never repay the Society for the benefits we have received.

The engineer has designed and built many a monument which will endure for ages as a testimonial to his proficiency and skill. We need not go back many years to find members who have won the highest engineering distinction and whose names are ineffaceably engraved on the enduring pages of history. We know who they are and what they have accomplished. Even before this Society was organized, we find the names of engineers who achieved everlasting remembrance through their exceptional ability. Therefore, I would say to engineers, but more particularly to the younger members of the profession, that there is a future for them which, if taken advantage of, will ensure the highest honors possible to be obtained.

By him who is in the prime of life and in the possession of health, strength, and knowledge of the arts and sciences, much may be accomplished. Therefore, never give up. Think, work and suffer, that in this life you may gain something which will place your name upon the highest pinnacle of fame.

Many of our members have been engaged in the late war, and their work, in the construction of yards, docks, cantonments, and the reconstruction and building of bridges, roads and equipment, both in this country and on the other side of the Atlantic, thus making it possible to take care of millions of troops, was the most important factor in bringing the war to a successful termination. All of this has been done in such short time as to bring out comment and praise from the whole world. Why should not the engineer have his full due and credit for the ability he has shown, not only at critical moments during the war, but in the accomplishment of things at other times?

We are living in an age in which we possess all the information as to what has been done for many years, all of which we ought to profit by. The conditions change, the opportunities grow greater. This world is growing in its necessities almost beyond the imagination of the present generation. The country is being developed so that every State in the Union is increasing in wealth and prosperity. Greater facilities are needed to accommodate its growth. And yet some say there is no future!

The work of other engineering societies or organizations should also be mentioned. They have all done their part in building and developing the great industries of the world. All are working toward the same purpose, creating, building, and improving the facilities on which the prosperity of the country depends. This is illustrated by the establishment of Engineering Council, composed at present of representatives of the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers, the American Society of Mechanical Engineers, the American Institute of Electrical Engineers, and the American Society for Testing Materials, for the purpose of giving more strength to the profession and obtaining greater recognition for the engineering arts and sciences.

Why should we not go farther, and even take our position in Governmental affairs? Is it the political cloud that casts a shadow over us, so that our practical ability does not get the proper recogni-

tion in Government affairs; or is it our modest, indifferent way of being satisfied with our present condition? We should rise to the occasion, demand our rights, and a proper recognition by the people generally, with the idea that we are not only to advance the engineering arts and sciences but to fill the positions under this General Government which require the knowledge of how to govern, each according to his ability.

The Armistice having been signed, it is incumbent on us, as founders of prosperity, with the sciences and the arts, to become one of the greatest upbuilding factors in the future, to help reconstruct that which has been torn down and destroyed by the ravages of war, and to promote new ideas for the world's future prosperity.

Emerging from the greatest war the world has ever known, not only in the number of men engaged and the use of the most deadly weapons, but in the destruction of property, what does this mean for the future? The employment of many engineers to reconstruct, and to rebuild in an improved form.

In the future the names of many of you engineers will be enrolled among those who have attained high public standing through great achievements. Many in our profession have thought, done, and suffered much in former days. Childhood may seem to be at almost an immeasurable distance in the past, but something that we have accomplished on account of its overpowering vastness seems near. It is like a beacon light, far away but seemingly near.

It is said, "The schoolhouse of the world—human experience—however expensive, has something to teach." Shall we learn our lesson readily?

Paper No. 1441

CONTRACTS—A COMPARISON OF "COST PLUS" WITH OTHER FORMS*

By Ernest Wilder Clarke, M. Am. Soc. C. E.

With Discussion by Messrs. F. Lavis, Missac Thompson, F. H. Frankland, J. Waldo Smith, Edward F. Hammel, Lazarus White, Arthur P. Davis, Henry H. Quimby, J. P. H. Perry, Henry B. Seaman, Frederick Glaeser, George D. Snyder, F. G. Baum, George Perrine, P. L. Reed, Walter H. Wheeler, E. G. Walker, J. A. L. Waddell, William E. Woolley, R. D. L. French, J. W. Ledoux, and Ernest Wilder Clarke.

Synopsis

1. This paper is presented in order to bring to the attention of the members of the Society the experience with the "cost plus" form of contract on Government construction work during the past two years, and to obtain from them an expression of opinion as to the advisability of a more general use of this form of contract.

2. The writer does not pretend to present any exhaustive arguments either for or against any form of contract. The paper is intended simply to form a basis for discussion, with the hope that, as a result of such discussion, some action may be taken that will be of advantage in future construction work.

3. The more or less self-evident objections to the lump-sum and item forms of contracts are mentioned, and some of the advantages

* Presented at the meeting of September 3d, 1919.

which can be obtained from the use of the "cost plus" form are also stated.

The use during the past two years of the "cost plus" form of contract on very large and complicated construction work seems to the writer to render the time opportune for a general discussion of the advantages and disadvantages of this type of contract.

In order to bring the matter before the Society, the following résumé of some of the more or less self-evident faults and virtues of the usual contract forms are presented, not with the idea of informing the members of the Society, but to establish a basis for discussion.

The usual methods of paying for work are by lump-sum, by item charges, and by cost plus a percentage. Under the first two methods, the contractor takes the engineers' or architects' specifications and estimates of the quantities, possibly checks the latter by his own computation, guesses at the interpretation which will be placed by the owner's representatives on the terms of the specifications and, from his knowledge of costs of materials and labor, makes up a bid.

In a lump-sum contract the preliminary estimate of quantities is final, as are also the original plans of foundations, details, etc. Any changes must be a matter of settlement between the owner and the contractor. The latter takes all the gamble, and if conditions or quantities turn out more favorably than was anticipated, he wins; otherwise, he loses, or is tempted to decrease the cost to himself by some method which generally means a poorer grade of work than that contemplated in the specifications. If conditions turn out much worse than anticipated by the contractor, he may forfeit whatever bond he put up and leave the owner and bondsman to settle. The owner very often desires to change the plans as the work progresses, either to cheapen the job or to add new features or improvements, and as there is no basis in the contract for payment to the contractor for such changes, a new bargain must be made. Generally, it is almost impossible to let additional work to a new contractor, so the owner is at the mercy of the original one and must submit to whatever terms he offers or forego the changes. The lump-sum contract has all the seeds of misunderstandings, disputes, lawsuits, and poor work, and not even the benefit of a pre-knowledge of ultimate cost, as there is almost invariably a long list of "extras."

In "item" contracts, the award is made on the sum of the products of the units in each item multiplied by the bid per unit. In most engineering work, the preliminary estimate of unit quantities is necessarily approximate—often the owner is unwilling on account of cost or unable for various reasons to make the investigations which would afford a basis for an exact determination. This is especially true of sub-surface structures, but even in superstructures quantities cannot always be computed accurately in advance. This is one of the great sources of disappointment to the owner in the ultimate cost of work let under this form of contract—of gambling on the part of the contractor and of loss or unfair cost to both.

The contractor and the owner may disagree on the interpretation of the data for the estimate—the contractor backs his judgment by bidding low on items which he thinks are over-estimated and high on those which are under-estimated. His total bid is lower than he would be willing to take the work for if the preliminary estimate of quantities was known to show also the final estimate, but allows a fair or better profit if the final estimate approximates that made by himself. In other words, the owner thinks he is letting the work to cost one sum, and the contractor expects to receive another and larger sum. Badly unbalanced bids are often thrown out, but a skillful bidder does not make his unbalancing so raw as to justify this action. This kind of bidding is not, *per se*, unfair or dishonest, and the ability thus to bid safely may be truly a part of the contractor's equipment, but it results in disappointment to the owner when he finds his final estimate largely in excess of that anticipated. If, on the other hand, such bidding is merely a wild guess or due to optimism on the part of the contractor, it is a gamble pure and simple which, if unsuccessful, results in loss to himself and often to the owner.

Item bids require as a basis a set of definitions. Some items are so self-evident that no confusion can possibly arise as to the meaning of the definition; others shade into other items, and it is hard to define the line of demarcation. Other items are described as containing certain materials in certain proportions, and any variation from these proportions constitutes a new item, more or less expensive. Another item is described as being a certain stock material or machine, and any variation ordered or permitted raises the question of cost to the con-

tractor. The possibility and even probability of argument and variation in cost, due to varied reading of definitions or changes in details of items, could be elaborated almost indefinitely, but enough has been said to illustrate how fruitful of bills for extra cost this part of the specification can be.

The "item" contract is better than the lump-sum in that changes in plan, due to the development of the work or the meeting of unforeseen conditions and variations in unit quantities, can be adjusted under the terms of the original contract, if the items included in that contract can be reasonably construed to apply to the new conditions; but it is still limited by the items which can be so construed and which both the contractor and owner are willing to admit are fair as to cost under these new conditions.

Applying to both these forms are several factors which are taken into account in their bids by all successful contractors and for which all owners pay indirectly. Some of these are the clauses removing responsibility from the owner for the accuracy of the preliminary data; for errors in laying out work; for refusing to accept the action of the owner's inspectors at the time of actual construction and retaining the right of rejection to the final inspection; for making the owner's engineer the final interpreter of his own specification and allowing him to supplement his drawings and specification in any way, in order to make the meaning conform to this interpretation. The contractor has to take the gamble that the original data are reasonably accurate, that the work of laying out will be carefully done, or else maintain an engineering organization to check the work—for which duplicate organization the owner will pay—that the engineers will be just, and that the original engineer will remain in charge throughout the life of the work.

Many specifications require tests of material which, if rigidly enforced, would often cause great delay and expense to the contractor or the carrying of a large stock, entailing interest charges, storage space, rehandling, and other expenses. The contractor usually expects that the purchase of material from well-known manufacturers or certificates from them will avoid the enforcement of these clauses, but if he is wise, he considers the possibility that they may be insisted on, and bids accordingly.

In short, the tendency of the entire specification is to remove responsibility from the owner and his representatives and place it on the contractor; also, all the gamble on weather, foundations, changes in labor and material market, and every other unknown or unknowable factor is carefully unloaded on him.

The contractor accepts all this, but the owner pays. The individual owner may save money, because the gamble went against the contractor on his job, but his neighbor loses, because in the long run the contractor must make money to live. The owner may lose by a contractor being too optimistic, getting a job partly done and then being unable to finish on account of high costs; re-advertising, re-letting, and delays follow, or else the bondsmen finish the work at a loss to themselves, which loss is passed on to other owners.

If a contractor makes an unexpectedly large profit, however, on Job A, he does not reduce his bid on Job B, in consequence, so that it is only the losses that are passed on to other owners and never the gains.

In "cost plus" contracts, the owner accepts all risks, all costs, and receives the benefit of all favorable conditions; each job carries its own load only, without the addition of losses on other jobs and without the percentage added by the contractor to offset possibly unfavorable conditions, ambiguous specifications, or captious owners.

The specifications and plans may be as general or as specific as the owner desires; changes can be made, difficulties met, and advantage taken by the owner of special machines, material, and methods.

The contractor furnishes the plant, organization, and expert knowledge of construction and buying; the owner supervises the work and pays the bills.

In the case of "cost plus" contracts, the contract and not the specifications is the crux of the matter from both the owner's and contractor's viewpoint, but the writing of the contract is more simple than the writing of the specifications. It is necessary first, to define what expenses are to be borne by the contractor, as not part of any one job. These may be head office expenses, salaries of chief officers whose time is spent only in part on the job, traveling expenses, except as agreed on, or the contractor's auditors, timekeepers, or material checkers. Second, to define what expenses are to be borne by the owner and are to form the basis for the fee. Such expenses would include the cost

of materials purchased through the contractor, the cost of labor of all grades, and the cost or rental of plant. Third, to define what expenses are to be borne by the owner, but which are not to be included in calculating the fee to the contractor. These might be engineering services, inspection, owner's timekeepers and auditors, and the cost of specified material which the owner elects to purchase and deliver to the contractor.

The approval of the owner would be required for all purchases of material both as to the necessity for the purchase and the price paid. The owner may reserve the right to enter the market with the contractor, purchase any material he can buy cheaper than the contractor, and deduct such cost from the total cost of the work for fee calculation. The owner would have control of the number, grade, and wages of all classes of labor, and, of course, would pay all insurance charges.

The sliding percentage with maximum fee, as used on Government work, could be applied to any contract, large or small.

Contracts could be let on the basis of fee demanded, both percentage and maximum, on the size, adaptability, and condition of the plant controlled by the bidder, and on his experience, reputation, and the size and character of his organization.

It is true that the interest of the owner to keep down the cost, and that of the contractor to receive a large fee, would clash, but that is controlled by the sliding percentage which can be arranged to give an actually larger fee for smaller total cost, and by the maximum fee which is based on the owner's estimate of total cost.

Capable, honest, efficient contractors would fare well under this form of contract; the opposite kind would soon find it impossible to secure work. Engineers of the two classes would meet the same fate as the corresponding contractors. The engineer would no longer be supposed to act as an arbiter when he is paid by one of the parties to the contract to supervise the work of the other and to secure work conforming to specifications and plans which he himself has drawn. The engineer is always biased, and no matter how hard he tries to be fair or how cordial the relation between himself and the contractor, in case of argument, the latter bears the burden of the proof. For this state of affairs the owner pays, and the successful contractor is one who has added enough to his bid, in one way or another, to make up for the

losses he suffers due, not to the work itself, but to the specifications. The writer believes that given the same men as owner, engineer, and contractor, a cheaper and better job can be secured by the owner and, in the long run, more profitable business to the contractor by the "cost plus" contract than by either the lump-sum or item bids. The owner will not be confronted by bills for extras, vexatious claims for adjustments due to different interpretations of the specifications, lawsuits with their attendant cost, and the perpetual chance that, in spite of inspection, poor work will be done by the contractor in order to secure a profit on an underbid item. The contractor will be sure of a reasonable return on his investment in plant, he will not have to pay for special plant of use to him only on that one job, or to carry the burden of the gamble on unknown or unknowable factors.

The gamble belongs to the owner who gains or loses by the location of the site, the season of the year in which the work is done, the state of the market for men, materials, and money, and circumstances other than strictly construction work, which affect the cost of the structure; and when contractors are relieved of this gamble, they can bid closer, they can put their energy and knowledge into efforts to turn out good work, and not be constantly on the watch to cheapen the work for their own benefit—maybe salvation—and the owner's harm.

It will be for the owner and his engineer to say where to cheapen, when to spend, to pay extra prices, if they wish, to speed up work, or secure quick delivery. The job is the owner's; he should handle it and take the profits and the losses.

There can be, of course, great dishonesty under "cost plus" contracts, but, if this occurs, it is the owner's fault in lax supervision of his own forces or from incompetent or dishonest engineers.

It is hoped by this paper to obtain an expression of opinion as to the wisdom of substituting "cost plus" contracts for the other forms. At the present time, municipal work is usually required by law to be let to the lowest bidder, and any violation of the custom, even when the law permits, affords a basis for accusations of graft on the part of the officials responsible, no matter how self-evident the lack of ability of the low bidder may be.

If "cost plus" contracts can wisely be substituted for the other forms, the writer conceives it to be a timely occasion to endeavor to have the laws amended so that municipalities as well as individuals can

take advantage of it, and also to draft a standard form of contract sufficiently elastic to be adaptable to all usual work, so that the possible disadvantage may be reduced to a minimum and that dishonest officials may be prevented from discrediting a method which, in the hands of honest men, can certainly produce economical, rapid, and good construction.

DISCUSSION

Mr. Lavis.

F. LAVIS,* M. AM. SOC. C. E. (by letter).—The author is evidently much impressed by the virtues of the so-called "cost plus" forms of contracts and the defects of the "lump-sum" and "unit" forms, but also evidently has a suspicion that there is a "nigger in the woodpile somewhere". It would seem to be almost self-evident that all three forms of contracts have their use at appropriate times and places.

The fact that the "cost plus" form has been used so frequently during the last three or four years, shows its adaptability to abnormal conditions, such as those which have existed during the war period when everything has been so unsettled that no one could conservatively venture a prediction as to the future. During this period, not only the Government, but manufacturers and others have required works to be carried out almost regardless of cost. It was necessary to employ existing organizations of both contractors and engineers and simply foot the bills, whatever they might be, and it is a high tribute to the honesty, integrity, and ability of both to know—as we do—that, on the whole, practically no undue advantage has been taken of this situation by either class and that most of the work has been carried out as efficiently and cheaply as was possible under the circumstances.

This state of affairs, however, is abnormal, and the methods used to meet it are seldom applicable to normal conditions. Usually, every one, from the builder of the smallest house to the greatest capitalist and investor, wants to know pretty closely what the cost is going to be before they start, and they are almost always willing to let the contractor take the gamble, if there is any. Often, however, he has had sufficient experience to be fairly sure in cases which would be pure gambling to others with less experience.

The author rather emphasizes the fact that, if the contractor has to take chances, he endeavors to cover himself by making an unduly high bid, but, on the competitive basis, this is at least partly controlled by reason of the competition. It is to be noted, however, that modern contracts and specifications for work to be carried out on a unit price basis reduce the chances the contractor has to take to a minimum. Splendid examples of this are the contracts used for the construction of the Catskill Aqueduct, by the Board of Water Supply of the City of New York.

The author points out the difficulties in regard to definitions, etc.; in other words, lack of skill on the part of engineers to describe what they want. Of course, it is true that difficulties do occur in the interpretation of contracts and specifications, no matter how skilfully they may be drawn, but many of these could often be avoided by the exercise of a certain amount of common sense on the part of the interpreters,

* New York City.

and, in any event, it is doubtful whether the causes for disagreement are more, or more often evident, in contracts based on unit prices than on the "cost plus" form, provided both are properly drawn and honestly and conscientiously carried out. Mr. Lavis.

Some of the objectionable clauses which cause trouble in connection with unit price contracts, pointed out recently by J. W. Rollins, M. Am. Soc. C. E., are as follows:

(1) Disclaiming responsibility for soundings and other information as to the character of the work.
(2) The insertion of the clause which may make any contractor's estimate and bid worthless, that is, "or as otherwise directed."
(3) Making contractors responsible for work for which the engineers make the plans, or requiring the approval of the engineer to any made by the contractor for temporary work, and in which the engineers reserve the right to control entirely the manner and means of construction.
(4) Holding the contractor responsible for work which has been built under the direction of the engineer, and has passed inspection, unless fraud and gross negligence is proved.
(5) Making the engineer the sole referee in settling all claims.
(6) The right to stop work, or any part of it, if it is to the interest of the engineer so to do, without allowing the contractor any compensation for such action.

The author points to similar clauses as increasing the cost of work carried out on a unit price basis. They do cause such increases, but they are indications of lack of engineering skill and ability, and should have no place in a properly and fairly drawn contract.

In considering the merits of any form of contract, it must be assumed that the same conditions will apply. For instance, it is useless to say that because the owner refuses to make proper sub-surface investigations, the unit price bid is a gamble. Under these conditions, any form of contract is a gamble.

The author thinks the contractor who bids in competition may bid high because of improper estimates of quantities. This is a confession of lack of sufficient engineering, or lack of engineering skill, the results of which can hardly be charged against a form of contract. If similar lack of skill is shown in connection with a "cost plus" contract, the result would be equally disastrous or expensive to the owner, if not more so.

Judging from some paragraphs of the author's paper, one would imagine that all bidders on unit price work were gamblers with the dice loaded in their favor, but the writer is sure that an extended acquaintance with the financial results of their work, year in and year out, would show that they make less net profit perhaps than the

Mr. Lavis.

majority of men in business who bring to their work an equal amount of skill, intelligence, and really hard work.

One thing must not be lost sight of in connection with "cost plus" contracts, that is, no matter how honest and conscientious the principals are, it is difficult to determine whether the actual output per unit of the men's time is as great on work done on this basis as it is on the lump-sum or unit price basis.

The theory that the engineer in charge of a contract is a referee or arbitrator between the owner and the contractor, the writer thinks will hardly hold in the Courts. As a matter of fact, engineers are so by courtesy, because usually they are held in high esteem by both their employers and contractors, and both, in many cases, are willing to abide by their judgment.

The author believes that with efficient honest contractors and engineers, better results can be obtained under the "cost plus" form of contract because "the owner will not be confronted by bills for extras, vexatious claims for adjustments due to different misinterpretation of the specifications", etc.

With honest capable contractors, there is seldom much trouble. The author must bear in mind, however, that with the unit price contract all the engineer has to do is to see that the quality of the work is good and that its performance is up to date. With the "cost plus" form, notwithstanding the reputation of the contractor—and with many it is very high—the owner's representative, if he is conscientious, will not only satisfy himself as to the quality of the work, but also of the honesty and efficiency of the contractor's organization. He can no more take for granted that pay-rolls are not padded, that outside commissions are not paid, or that the men or the organization are efficient, than he can take for granted the depth of a foundation, the quality of the soil, or the acceptance of Portland cement or steel without testing.

The author asks the specific question as to the desirability of adopting the "cost plus" form for municipal and other public works. Under war or similar conditions it may be; but, for normal conditions, no. The writer has had some experience and vexation in connection with the red tape, etc., thrown around the letting of municipal or other public works contracts. The award to the lowest bidder is often a cause of expense, but, by and large, and taking into consideration all the facts, it will be found that there are many good reasons for the various regulations and safeguards thrown around the actions of municipal and governmental officers in the expenditure of public funds.

Besides all these things, there is also the important item of predetermination of total cost. Of course this is accomplished to a certain extent in those forms of the "cost plus" contract which name an

estimated total cost with a sliding scale fee increased for keeping within the total, and decreased for exceeding it, but there is not the same assurance—which is often desirable—with this form as with others. Mr. Lavis.

It seems hardly feasible to define exactly what kinds of work or what set of conditions warrant the adoption of one or another form of contract, but, in general, the following may be suggested:

a.—For certain forms of work, involving clearly defined materials and easily determined quantities, where important changes are not probable, and where the size of the job is not too large, the lump-sum form of contract is indicated.

b.—For forms of work, where specifications can be drawn, which will define reasonably clearly each class of work to be performed, but where only approximate determinations of quantities can be made, the unit price form is indicated.

c.—When conditions are such that the work to be done cannot be defined reasonably clearly and definitely, or when the period of construction extends over such a long time that it is difficult to forecast conditions so far ahead, or in a time like the present, when everything is so disturbed, there is little option but to adopt the "cost plus" form.

The writer realizes, of course, that these conditions overlap, and that many others may influence the decision, but, in this, as in everything else, the skilful experienced engineer will realize the conditions, and, being informed as to all the different kinds or forms of contracts, will advise his client accordingly.

Missac Thompson,* Jun. Am. Soc. C. E.† (by letter).—For purposes of this discussion, the writer will classify contracts as long-time and short-time. Without trying to draw a line of demarcation, he will state that the long-time contract is one, the fulfillment of which will take sufficient time to anticipate marked changes in the market prices for labor and materials; whereas, the short-time contract is one, the fulfillment of which will not take sufficient time to make appreciable difference in the market prices of commodities for the particular work. Mr. Thompson.

This division cannot be made in terms of time measure alone, other circumstances, such as the political and economical situation of the country, the particular contractor, and his organization, are also factors to be considered.

Long-time contracts, if based on preliminary designs, are not often drawn on the lump-sum basis. If such contracts are drawn on the basis of item charges, again, both sides are gambling.

It is very difficult, if not impossible, to define what might be acceptable material or workmanship. In such construction as rein-

* Brooklyn, N. Y.

† Now Assoc. M. Am. Soc. C. E.

Mr. Thompson.

forced concrete, with the ordinary method of inspection, the owner or his representative has no practical protection against dishonesty or negligence on the part of the contractor.

It seems to the writer that, in long-time contracts, the interests of both parties—owner and contractor—will be safeguarded, if all the materials forming a permanent part of the job are furnished by the owner, and the contractor simply bids on the actual construction on a labor-day basis for the unit of work.

This mode of contract can be illustrated by an example: Suppose Jones wants to build a reinforced concrete factory, and Smith is the contractor for the job. Jones furnishes all the permanent materials for the work; Smith bids on furnishing the timber for forms and erecting the form work at one-fifth carpenter-day per square foot of form; or, on mixing and placing the concrete at one-half labor-day per cubic yard, etc.

In some cases, the contractor by superior knowledge of market conditions may obtain materials to better advantage. In that event, his services may be made use of and paid for as such.

The owner by furnishing the materials is sure of getting what he wants. He is relieved of rigid inspection obligation, because faulty workmanship will always show. He can get more competition for his job, because much less outlay of capital on the part of the contractor is necessary. In most cases, the owner, with his ready cash, is in a better position to bargain for the materials.

On the other hand, the contractor is relieved of probable rejections, disputes, etc.; he saves time by doing away with a lot of unnecessary checkings, markings, etc.; and he is safeguarded against wage increases, strikes, etc.

In some cases, the same basis may be used for short-time contracts as that suggested for long-time contracts. However, in many cases, this procedure is impractical:

First.—The owner usually finances the work by borrowing from banks or individuals, and the loan cannot be arranged to pay for materials as they are delivered.

Second.—It is more practical for the owner to pay somewhat more and know beforehand the cost of the work, in order to arrange for his financing.

Third.—Very close estimates of materials and labor can be made beforehand, and the contractor's percentage of profit on small jobs is necessarily larger and the elements of uncertainty are less.

Fourth.—Even if bids are taken from preliminary designs and estimates, a clause may be inserted in the contract terms, by which additions and subtractions may be taken care of.

It seems to the writer, therefore, that, for short-time contracts, the lump-sum basis is practical and desirable. However, the "cost plus"

definite fee or the cost plus percentage method of contract is objectionable, because it kills competition which is the key to efficiency. It offers undeniable opportunity for favoritism on the part of the owner's representative. Moreover, it is out of the question to persuade most investors, who borrow to finance their enterprise, to let a contract on the cost plus percentage basis. Mr. Thompson.

F. H. FRANKLAND,* M. AM. SOC. C. E.—The author states that he does not pretend to present arguments either for or against any particular form of contract, but a reading of the paper shows that it is only a brief for the "cost plus" system. In fact, in the author's remarks just preceding the opening of the oral discussion, he admitted that this was true. Mr. Frankland.

Most of the worst features of lump-sum and unit-price contracts are discussed in the paper, whereas nothing objectionable is mentioned as relating to the "cost plus" system. In the speaker's opinion, based on a great many years' experience in the supervision of engineering construction, all the ordinary forms of contract, as exemplified in lump-sum, "cost plus", and unit-price work, have serious drawbacks.

In one place, in his paper, the author makes the serious charge that the engineer is always biased, and no matter how hard he tries to be fair, no matter how cordial the relation between himself and the contractor may be, in case of argument the latter bears the burden of proof. This is a pretty strong statement, and the speaker considers it a somewhat unwarranted aspersion on a large number of engineers, possessed of experience, principle, integrity, and (to use the Shakespearian expression) engineers with "guts", who are absolutely without bias against contractors. Many instances could be cited where supervising engineers have fought hard and successfully for a square deal to a contractor.

The speaker mentions this because it is one of the stock arguments which is always brought up, when "cost plus" contracts are discussed. The war is over, and conditions have changed more suddenly and more completely in a given time than ever before in the recollection of most of the members of the Society, and the present seems to be the psychological moment for the engineers and contractors of the United States to "get busy" and do something about forms and bases of contracts. It is generally admitted that a large amount of foreign engineering and contracting is now open to American engineers and contractors, if they will only go after it in the proper way.

One of the serious disadvantages of the ordinary kind of "cost plus" contract is the lack of incentive for the contractor to complete the work at the lowest legitimate cost. The ideal form of contract should provide for the best possible workmanship at the lowest legitimate cost.

* New York City.

Mr. Frankland.

The ordinary forms of "cost plus", lump-sum, and unit-price contracts do not fulfill these requirements, and the time has arrived when something should be done toward improving the methods of letting construction contracts now in vogue. It must not be imagined by any one that an ordinary "cost plus" basis for foreign contracts will be acceptable to the owners. This form of contract is rightly looked on abroad with suspicion.

If the whole truth was known regarding some of the "cost plus" contracts let in the United States during the past few years, this form of contract would "smell to high heaven." Of course, we all know that it was absolutely necessary to let a great deal of work during the war on a "cost plus" basis in order to get it done, but to the speaker that does not seem to be a valid excuse for the continuation of that form of contract.

Mr. Smith.

J. WALDO SMITH,* M. AM. SOC. C. E.—The speaker is one of those who believe that, under certain conditions, there is a proper use, and even necessity, for each of the forms of contracts outlined by the author, although he does not at all share the opinion as to the desirability of the general use of a "cost plus a percentage" or "cost plus a fixed sum" contract, or the difficulty of carrying out a regular itemized form of contract without including "extra work."

If the plans are so indeterminate and the investigations so incomplete that it is impracticable to form an estimate of the total cost within reasonable limits, then, without doubt, the "cost plus a percentage" contract is the only one which fits the case, especially if great expedition is required. If, however, it is possible to make an estimate of the total cost within reasonable limits, then some form of the "cost plus a fixed sum" contract is entirely practicable and to be preferred to the "cost plus a percentage" contract.

If work was to be done generally by either of these "cost plus" forms of contract, it would certainly lead to the grossest discrimination and favoritism, would prove an insuperable obstacle to the proper development of the contracting business, and tend to destroy the incentive for the study of new methods and the exercise of the greatest resourcefulness in conducting the work. It would also exclude the gambling element which has so strong an attraction for the average contractor.

Under the conditions which have prevailed during the past two years, and the enormous volume of work done without the preparation of detailed plans, where many of the conditions were indeterminate and where great expedition was required, it was undoubtedly necessary to use both the "cost plus a percentage" and some form of "cost plus a fixed sum" contract. In the majority of cases, it is believed that the general type of contract used by the Construction Division of the

* New York City.

U. S. Army, of "cost plus a sliding percentage with a limiting sum", or one of its variations on the same principle, was entirely practicable, but there was little need for a "cost plus a fixed percentage" contract. Mr. Smith.

The author, both in his paper and in his remarks when presenting it before the Society, seemed to have a decided leaning toward a "cost plus" contract for ordinary use. For engineers to advocate such a form for general use is, in the speaker's opinion, a confession of weakness—that engineers are unable to draw contracts and specifications, founded on ample investigations and full information, which are fair to both parties to the contract and on which bidders can make an intelligent and safe proposal.

It is well known that engineers in charge of public work are handicapped in drawing contracts as fair to the parties thereto as they desire, by reason of limitations imposed by the law departments of municipalities or States. These restrictions are largely the result of previous experiences in Court, and the legal authorities seek, by injecting arbitrary clauses into the contract, to prevent recoveries in the future, rather than to make the contract so fair between the parties to it, that there would be in general no incentive to bring action thereafter.

The engineer is often confronted, in the preparation of plans, with a great cry from principals, who may be either private individuals or public officials, to see the actual construction work started before the necessary investigations have been completed. Nothing is more vicious or sure to lead to trouble afterward.

If the contractor is not given sufficient information, if the known difficulties are not set forth, if the proper investigations have not been made by those who have been on the job for months, if it is not clearly stated just what is to be done under each item and how payment is to be made, and if everything reasonable is not done so that the contractor can size up accurately the conditions with which he will probably be confronted, and submit an intelligent bid, trouble is almost certain to develop during the progress of the work and cause litigation afterward. If, however, all this information has been obtained and spread before him, and he is given a fair show and not treated arbitrarily, not only would he fail to collect much through the Court in case of litigation, but the average contractor would not even bring legal action.

Mr. Hammel.

EDWARD F. HAMMEL,* JUN. AM. SOC. C. E.†—The technical press has been devoting a great deal of time and space to this subject of contracts, and all engineers have had various experiences with the matter of contract forms. The speaker will limit his remarks on the subject very largely to building work, to which his experience has been confined.

The speaker asked four contractors to bid on a certain job, and of

* New York City.
† Now Assoc. M. Am. Soc. C. E.

Mr. Hammel.

these, three wanted the work on a "cost plus" basis. Since the owner wanted to know how much the job was going to cost, this form of contract could not be considered. This owner knows how much he can reasonably get for the floor space of the building which he proposes to erect; he also knows about what his taxes and operating costs will be, and, in the light of these facts, he knows about how much he can spend on the erection of the building and still obtain a fair return on the investment. If he cannot get enough interest on the investment he proposes to make, he will not feel warranted in going ahead with the operation. Finally, one of the contractors returned the plans and specifications, stating that, due to the present unsettled conditions of labor, he was unable to undertake the work on any other basis. After arguing on the merits of the "cost plus" contract, the other two finally agreed to furnish lump-sum bids, but stated that ultimately it would cost the owner more than on the "cost plus" basis, because they would have to add a large figure for contingencies, which might be avoided if they went ahead on a cost plus a fixed fee or a cost plus a percentage basis.

It seems to the speaker that the various forms of contracts which have been drawn, have been designed to fit special conditions, and as long as the labor market was fairly stable and wage agreements were adhered to by labor—there have been agreements in the past, which have lasted a certain time—and as long as the prices of materials were stable, there seemed to be no particular reason why a contractor could not submit an estimate on the lump-sum basis and finish the job with a reasonable amount of profit. Certain contingencies might arise which would reduce that profit, and others which would increase it, but the contractor was reasonably sure of finishing the job with his overhead covered and a certain amount of profit.

During the war period, conditions were entirely different. The Government speeded up its work, because the buildings had to be erected almost immediately. If they had been erected a year later, they would not have contributed anything toward winning the war. The Government officials were not able to make exhaustive investigations; they did not have the data, nor the time to get them, and it was absolutely essential that some form of contract should be adopted, which was fair to the contractors, otherwise they would not have taken the work. The only way out of it, apparently, was to tell the contractors to build the necessary structures, etc., on some form of "cost plus" contract. The Government chose contractors who had organizations large enough to do the work on a speedy basis, and said: "We will pay you for the cost of the work and for your services", and it seems that the "cost plus" contract was the only form which could have been adopted to meet the emergency.

Addressing a man who was on the contractor's staff on one of the cantonment jobs, and who spent a good part of his time riding to and

from the city in an automobile, the speaker said, "You must be making a lot of money". To which he replied, "Oh, no, the Government is paying for this". That, perhaps, was a little item, financially, but it was an indication of the wastefulness practiced on "cost plus" jobs. At times, something has to be sacrificed, and the Government made the sacrifice of money in order to obtain speed. Mr. Hammel.

It may sometimes happen that the owner of a manufacturing plant, such as an automobile factory, may want to extend that plant. He is very anxious to get his addition completed, and he does not care if it costs 10% more than the possible lowest cost, provided he can get it done speedily; therefore, it may seem to him that the "cost plus" is a fairer contract, and, perhaps, it is under these special circumstances. He is willing to sacrifice a financial saving in order to have the building put up more speedily.

On the other hand, a man who is contemplating building on a certain lot, and investing a certain amount of money as an economical investment, can afford to wait a little longer and have his building put up in accordance with a complete set of plans and specifications.

It seems to the speaker that the advocates of the "cost plus" contract miss certain points. They state that for the contractor it is the only fair method; that building contracting is a gamble; that it is so much of a gamble that the owner ought not to expect the contractor to make a fixed bid; and that he (the owner) ought to take a chance on a "cost plus" contract.

There is no more of a gamble in contracting within certain limitations, than in any other field of business. If the men engaged in the building business were generally to adopt the "cost plus" form of contract, an era of uncertainty would be reached in the cost of buildings, which would greatly restrict construction operations.

The gamble, as the speaker sees it—possibly he may be wrong—is almost entirely related to labor costs. There is no reason why the architect or engineer cannot prepare a complete set of plans and specifications and cover every item. There is no reason why an engineer or quantity surveyor cannot study these plans and specifications and take off accurately the quantities of materials which will be necessary to complete the structure, as accurately, or more so, than the engineer can compute his loads and stresses; and there is no reason why the contractor cannot take this as a basis on which to compute his construction costs. Then all the contractors will be bidding on the same quantities, and not on quantities which may vary greatly, due to erroneous estimations by their own staffs. They will all use the quantities prepared in the engineer's office, and the only thing that will vary is the cost of the labor necessary to put those quantities in place.

It seems to the speaker that some basis of adjustment, due to changes in labor wage scales, can be made. Let the contractor figure

Mr. Hammel.

on the current labor prices at the time he is making his estimate. He can order his building materials and cover himself on this cost for some time in advance. Future contingencies as to labor costs might be met by an additional stipulation in the contract; for instance, if a provision was put in the contract that if the cost of labor is increased, or if the present or prevailing rates are increased by circumstances not within the control of the contractor, the owner agrees to stand all, or perhaps a part, of such increase, so that the contractor would not lose much on that score, and the owner would be paying only for what he gets.

Then, there is the matter of incentive. As a matter of fact, the speaker knows of some jobs where the lump-sum is favored at the expense of the "cost plus" job. If a contractor is handling three or four jobs, and one happens to be on a "cost plus" or percentage basis, and the others happen to be on the lump-sum basis, and he has any bricklayers who are able to lay more bricks than others, he will keep his good men on the lump-sum jobs and send the "cripples to the hospital"; that is what these "cost-plus" jobs have been called. Three or four men get on the end of a rope, and somebody asks, "What are you doing there?" and finds out that all they are doing is holding the end of the rope; that is the way it goes on the "cost plus" job; there is no incentive to reduce costs. On the lump-sum job, however, the incentive to the builder is to get his work done at as low a cost as possible; he is not going to let his men loaf.

To be consistent the "cost plus" contractor should let his subcontracting work on the "cost plus" basis, but he does not do that. On the average every building contract has a general contractor and, perhaps, 15 or 20 sub-contractors, say, there are 15. The general contractor will often handle his own masonry and carpenter work. The speaker asked one of these contractors who was arguing that it was not fair to ask him to bid on a lump-sum basis, "How do you do with your sub-contractors? How about these fellows? How much work do you do yourself?" He replied, "We do 30% of this ourselves." Frequently, however, they do not do more than 20% of it. The speaker then said to this contractor, "Of course, you work on a percentage basis with all your 'subs'?" He replied, "Oh, no." The contractor will not show that element of fairness to the "subs" which he asks the owner to show to him. He would be willing to tie every one of the sub-contractors down to a lump-sum contract, and whether or not they were losing money, he would hold them to the letter of these contracts. If they are losing money, he says, "If you won't finish up under this figure, the surety company has got to make good on it", while he himself is safeguarded against any possible loss. If the "cost plus" contract is to be adopted, it ought to benefit more than the general contractor who is often a

looker-on in this game; it ought to be parceled out to every sub-contractor on the job. Mr. Hammel.

There is one other thing: If we carry this form of contract to its ultimate conclusion, who is going to get all these percentage jobs? There are certain contractors who have no organizations, and they depend on those who have to build the work, to get it out at a lower cost than their competitors; and they often get jobs on that basis without having the organization to complete them. If this lump-sum type of contract that is so unfair, is abolished and the "cost plus" or percentage contract is universally established, who is going to get these nice "soft" jobs? The "inside" man is the one who will be favored. An owner is not going to ask half a dozen contractors to bid as on a "cost plus" job. He is going to pick one man and engage him to handle the matter. The result will be that all the contractors who could go in on a competitive basis to get the business, simply will not know of the work or the owner. Gradually, they will disappear, and after awhile only a few of these favored contractors will be left, who will be making all the money. If a competent young engineer with a little money, some practical experience, and a lot of ambition, wants to get into the game, there will not be any use of his attempting to do so, because he will be "squeezed" out. He may be a good competent man and have a lot of push, but he will not get anywhere. He cannot go out on the basis of merit and get a job; he will have to "know" somebody in order to be favored. His early years must be spent in making acquaintances.

It seems to the speaker that, after all, under the "cost plus" contract, the contractor ceases to function as a business man. He becomes, not a man who has to use his shrewdness, his executive ability, and his brains to maintain an efficient organization and keep its operation within a reasonable cost, but simply a supervisor of labor, a superintendent of construction, and a material purchaser, and, as such, is very highly paid. All he has to do is to see that the other fellows do their work. He parcels out the work to others and looks it over. He will have degenerated from his present position. Sooner or later, he will be found out, and then he will be found out of a job, for there is no reason why the engineer cannot supplant him. He can sublet what work he wants to, purchase the materials, and supervise the construction for his client; he can add that much to his fee, and then, perhaps, engineers will be able to make a reasonable living.

LAZARUS WHITE,* ASSOC. M. AM. SOC. C. E.—The speaker believes that engineers have an idea that all contractors are in favor of the "cost plus" form, because it makes an easy and safe job for them. He believes that this paper, as he reads it, advocates the "cost plus" system. Mr. White.

* New York City.

Mr. White. at least, it gives arguments in favor of it and arguments against other forms of contracts.

The speaker has had experience both as an engineer and a contractor, and this experience has led him to believe that the old form of letting contracts on a competitive basis is much the best. The great objection to the "cost plus" contract is the means of getting it. There is a moral question which outweighs the question of cost. If the public in the long run is getting something that is not right, they are the ones who suffer. There is something straightforward in letting a contract on a competitive basis, if the job is properly prepared, say, like the contracts of the Board of Water Supply of the City of New York, and the contractors are invited to bid.

They form their own opinions as to what it is going to cost them; they put up a bond; the man who is low is taking some chance, and if the owners have not a very good reason for turning him down, he ought to get the job. Suppose the Board of Water Supply, through its chief, wanted to get a man on a "cost plus" basis. How would he do it? The speaker believes he would not know how to do it. The usual way would be to have a lot of people running around telling what great men they were, that they had the organization, etc.

When a man gets a job, he intends to make the best showing possible. What kind of work will he get from subordinates? How long does it take them to realize that they are on a "cost plus" basis? Every superintendent is met by this question, "It is not coming out of your pocket, is it?" And the same argument comes from laboring men.

A contractor on a "cost plus" job is not a contractor, he is an accountant; and nine-tenths of his time is given to demonstrating that he paid right prices for everything that he bought, and accounting for every cent expended; and that is the principal thing. It is not a question of efficiency any more; that is swallowed up. There is ten times more accounting on a $1 000 000 contract at "cost plus" than there would be on the same $1 000 000 of straight contracting.

Besides it eliminates the gamble. If a man takes a $1 000 000 contract (it is attractive, it must be said), he may make $100 000. In an ordinary contract, with good management, but on a "cost plus" basis, he is a few thousand dollars ahead of the job at the end of a year's hard work trying to demonstrate that he is not a crook.

There is another inherent difficulty: If the "cost plus" was carried to its logical conclusion, nobody would know what anything would cost, because certainly the total would be the sum of a number of "cost plus" jobs; and what would that total be? It seems that, on public work, in the long run, the "cost plus" contract could not be tolerated, because public work is done against definite appropriation on a "cost plus" job. When a city lets a job for $1 000 000, it is committed to

$1 000 000. When it lets a job on a "cost plus" no one knows to what it is committed. The same thing applies to the individual. Mr. White.

The speaker is simply giving his experience as an engineer and a contractor with both styles of construction.

ARTHUR P. DAVIS,* M. AM. SOC. C. E.†—The form of contract suggested by J. A. L. Waddell, M. Am. Soc. C. E.,‡ is excellent, if it can be carried out, but its use requires that all details be thoroughly well known in advance. Mr. Davis.

Now, those who have had experience on very large jobs, realize that it is very difficult in all such jobs to know the details in advance, and it is absolutely impossible in others. For instance, how is any contractor going to know all the details of a job on a foundation that has to be put down 100 or 150 ft. below the level of the ground, until it is actually opened and dug out. He can do all the boring, and all the guessing, he pleases, and yet he does not know how it is going until it is open. Such work always involves a big element of risk, as does also every long tunnel that passes through a high mountain. However closely it may be examined, there is a large element of uncertainty in the conditions that are to be encountered by a contractor who takes such work on any kind of a basis except a "cost plus" basis.

The term, "cost plus", is very indefinite. There are two radically different methods of "cost plus" contracts. One is to pay the cost plus a percentage and the other is to pay the cost plus some fixed sum. They are radically different, as different as the east is from the west. The speaker recognizes the fact that there were conditions at the breaking out of the war, which had to be met by rather unusual methods; but he has talked with both engineers and contractors who were engaged in the "cost plus" work, and has yet to find one who could convince him that it was not possible to have let those contracts on some other basis than to place a premium on extravagance and waste. In other words, to find out closely enough so that some fixed sum could be named as compensation for the use of the contractor's skill, equipment, and organization; or, still better, that some method could not have been outlined by which he could have received just compensation, and, in addition, a reward for properly ascertained economies—economies both of time and of money.

If a contract is let on the basis of cost plus a fixed sum, the contractor will earn his fixed sum sooner if he rushes his contract through and closes it up in a short time, which is the great consideration in the case of preparation for war. Deliberately, that incentive was taken away from the contractor.

We regard the great judges of our all-powerful Courts among our highest class public officials. They should be, and usually are, selected,

* Washington, D. C.

† Now President, Am. Soc. C. E.

‡ *Contracting*, September 15th, 1919, p. 178.

Mr. Davis. with great care; men who are just, who have an incentive higher than personal gain, as far as human beings can be found who do; and yet we find it to be a universal rule in all the Courts, from the highest to the lowest, that a judge shall not be permitted to sit in judgment in a case in which he is interested, because it is humanly impossible for him to eliminate his personal interest from his actions and his determinations.

Now, that is just as true of contractors as it is of judges. Even the contractor's own subordinates, his own employees, know that he has interests a certain way; that it is to his interest to make it cost more, because in that case he gets a larger fee; and temptations are such that it is absolutely necessary to guard against contracts of that kind. Assuming, however, that those who know more about the circumstances than the speaker, are right, that the "cost plus" contract was unavoidable in the haste of preparations for war, let us not lend any influence to extend that pernicious practice in ordinary work. Let us find out what the work should cost, as nearly as possible, and where it can be determined well in advance, the unit price contract, with fairly drawn specifications, is, as far as the speaker's experience goes, the fairest of all methods.

In that case, engineers have the opportunity of reasonable changes without affecting materially the profits of the contractor, if he has made a well-balanced bid; and in the case of earthwork, at least, and many other kinds of work, it is impossible to tell in advance how each of the units is going to run. A classification will be carried on as the work progresses, and the different classes put on a unit basis, so that the errors of estimate in advance will not greatly affect the profits, because where the material is harder, it commands a higher price for a higher classification.

It is at least logical and practicable, and is likely to make it to the interest of every man connected with a piece of work, to do the work right, and do it economically; and let us not assume that people are superhuman, and do not, and will not, look to their interests in getting out their work.

Where work is of such uncertain outcome, or is likely to involve many changes or much hazard, a contract let on a cost basis with compensation to the contractor, to be paid after a manner similar to that suggested by Mr. Waddell, is the best solution, even if the uncertainties leave more uncertainty as to the contractor's compensation, which is not nearly as bad as to leave him with a possibility of heavy loss, or to offer him a substantial premium for extravagance and waste.

Mr. Quimby. HENRY H. QUIMBY,* M. AM. SOC. C. E.—A large proportion of construction contract work is done for the public—the owner is the public, either Municipal, State, or National—and, in such work, competition

* Philadelphia, Pa.

is essential. Is there a practical and satisfactory scheme for securing competing bids on a "cost plus" basis? A limit of expenditure in every such contract is also essential, and as the limit must be fixed before the contract is delivered, and, therefore, before the work is done, an under-estimate might cause the serious embarrassment of reaching the limit before the completion of the necessary work. Mr. Quimby.

"Cost plus", whether it is plus a percentage or plus a lump sum fixed or variable, sounds fair, and if by it the owner gets just what he pays for, it is fair; but we must conclude from what we see and hear that that result is not commonly secured. If the contractor's compensation increases directly with the cost of the work, the system puts a premium on extravagance, as Mr. Davis has stated. It certainly may operate to eliminate all ambition on the part of the contractor to show his superior skill and efficiency as such, even if it does not induce him to nurse the job.

Only a few days ago, a division engineer complained to the speaker of the slow progress being made on the force account portion of a certain contract, and declared that he always noted a marked difference between the spirit in which the percentage portion of the contract was done and that in which the work was performed on the fixed-price portion by the same men. When it was suggested that the men need not know that the work is on a separate account, he replied that the men always know, and invariably produce less.

The sliding scale of compensation based on the relation of the actual total cost to a guaranteed maximum sounds logical, as tending to induce effort and promote efficiency, but a guaranteed maximum cost to the owner necessarily involves a risk of loss to the contractor, to avoid which is one of the arguments for the "cost plus" idea. Also, in case competition for the contract is necessary—as for public work—the sliding scale for compensation would have to be prescribed in the specifications, and the bidding would have to be on the guaranteed maximum, the temptation to take chances by a bidder being, therefore, much the same as in straight lump-sum contracting.

As the guaranteeing of a maximum cost will require the bidder to make a careful estimate, the plans must be definite as to the extent of the work and as complete as for a straight lump-sum bid, and this requirement eliminates one of the principal arguments for the "cost plus" contract.

If the bidder must take a risk by guaranteeing a maximum sum, why should he not have all he can save out of it; and if he must share such savings with the owner, why should not the owner share any loss that may result through an excess of actual cost?

In "cost plus" work, the necessity for checking the contractor's costs involves not only the additional cost of services, which may be quite appreciable, but is likely to occasion disputes and develop unpleasant

Mr. Quimby.

inquisitorial procedure, leading to direct supervision by the owner's representative of all the operations under the contract—purchase of material and direction of work—a situation under which a real contractor will not be happy, and which, pursued logically, will tend to dispense with his services. In the Graff system, described in "Bridge Engineering", the contractor stipulates that he "be left absolutely untrammeled and allowed to enter the buying market and otherwise to conduct his operations as though he were executing a straight contract."

There is a form of contract which, although giving the contractor an opportunity to develop his best methods of operation and win both the contract and a profit on it by his skill and energy, provides reasonably for both changes in plans and some kinds of contingencies. This is a lump-sum contract for the definite construction shown by the plans, together with unit prices for the various classes of work and material involved, these prices being applicable to changes in quantities—in full to additions and a reduced amount, say, one-half, to deductions. For any class of work not covered by such unit prices, a force-account item is also provided, the percentage to be bid in the proposal the same as the other prices. An aggregate of a bid for comparison of bids is obtained by extending the unit prices and force-account percentage on assumed quantities, and adding the extensions to the lump-sum bid for the work shown; thereby competition is secured throughout. In the event of changes being desired, which the unit prices do not specifically cover, or which create conditions not contemplated and make the bid price unfair, or, in case obstacles are encountered for which the contractor has not assumed responsibility, a special dicker is necessary, and, in such a dicker, the party of the second part to the contract is ordinarily quite as potent as the party of the first part.

The plans ought to be as complete as possible before the contract is made, and if an owner is not so prepared and goes ahead on meager data, he must expect to pay more in one way or another. If the plans can be made definite, so that quantities can be determined and under-surface conditions be reasonably explored, the greatest satisfaction to the owner, engineer, and contractor will generally be secured by a lump-sum contract or a fixed unit price contract with equitable provision for adjustments.

Mr. Perry.

J. P. H. PERRY,* M. AM. SOC. C. E.—The impression gained by the speaker from the discussion on this subject, seems to be a fairly common one, namely, that the cost of work, that is, the unit cost under the "cost plus" form of contract, is higher than for similar work done under a lump-sum or straight contract basis.

The Turner Construction Company, of New York City, of which the speaker is a Vice-President, has had an experience which would

* New York City.

Mr. Perry.

contradict that impression. The Company is in the building business and has erected nearly 600 reinforced concrete factory, warehouse, and other industrial buildings since May, 1902. On this work it has been found consistently that lower unit costs have been obtained on jobs done on a "cost plus" basis than on those for which the contract was a lump-sum or straight contract. Of nearly 750 contracts which have been handled to date, the division between the lump-sum and "cost plus" types of agreement has been nearly "fifty-fifty."

At the request of the editors of *Engineering News-Record,* in the spring of 1919, the Company investigated its cost records to see what conclusions could be drawn from cold facts and figures as to the effect of the type of contract, that is, lump-sum or "cost plus," on unit costs of building work. In order to get the comparison, the Company had to go back to 1917.

During this year, it built 22 factories or warehouses of reinforced concrete, on each of which the contract exceeded $100 000. The average for each of the 22 jobs was $413 000, which makes each building a fair-sized building contract. Of these 22 buildings, 13 (averaging $470 000 each) were built under a "cost plus" form of contract and 9 (averaging $329 000 each) were built under a lump-sum contract.

By a remarkable series of coincidences, the buildings that were "cost plus" or lump-sum parallel one another in the outstanding features, which, on a critical examination of the cost records, might be thought to affect the costs. That is, for every "cost plus" job, the Company had another, generally similar in size and location, under a lump-sum contract. Similarly, for every beam and girder "cost plus" job, there was a beam and girder job on lump-sum, and, in the same way, flat slab jobs, brick veneer jobs, and in-town and out-of-town jobs matched up fairly well.

It has been the Company's experience that, for purposes of comparison of the cost of buildings, three labor units and a general expense item taken together serve as a very accurate criterion as to the relative cost of the complete building. These are, as itemized on the Company's accounting system:

Item 3-F.—This item includes the cost of carpenter and labor work per square foot of floor required for placing and removing floor forms, including all hoisting and miscellaneous work in connection therewith. This item does not include the cost of making the forms before they are used for the first time and, therefore, a comparison is possible as between buildings having a different number of stories.

Item 22.—The cost of labor per cubic yard for all work in connection with the mixing and placing of concrete is included in this item. An average of this unit will give a very fair comparison.

Item 30.—The cost of all labor per ton for receiving, handling, bending, and placing steel reinforcement is kept under this account.

Mr. Perry

As the labor conditions under which this work is done, differ in the metropolitan districts from conditions existing outside of these districts, one comparison is made between jobs in the metropolitan districts and another between jobs outside of such districts.

Item 19.—This includes the general expense expressed as a percentage of the total pay-roll for the job. This item is included to show that the units obtained on Items 3-F, 22, and 30, were not influenced by incorrect charging of labor to general Item 19, thereby reducing the amounts properly chargeable to the cost of forms and the placing of concrete and steel.

The figures on these items for the jobs in question are shown in Table 1 which should be self-explanatory.

The speaker would like to call attention to certain factors back of the figures quoted in Table 1.

TABLE 1.—COMPARISON BASED ON A STUDY OF COST UNITS ON ALL FACTORIES AND WAREHOUSES COSTING MORE THAN $100 000, BUILT BY TURNER CONSTRUCTION COMPANY IN 1917.
Total Number, 22.

	Average unit on 13 percentage jobs.	Average unit on 9 lump-sum jobs.	Percentage jobs were cheaper by:	Lump-sum jobs were cheaper by:
Item 3-F: Cost per square foot of placing and removing floor forms	5.75c.	6.25c.	8%	.....
Item 22: Cost per cubic yard of mixing and placing concrete	$1.02	$1.04	2%	.....
Item 30: Cost per ton of receiving, bending, fabricating, and placing steel reinforcement on jobs in the metropolitan districts	(10 jobs) $15.71	(4 jobs) $14.89	.....	5%
Item 30: Cost per ton of receiving, bending, fabricating, and placing steel reinforcement on jobs outside of the metropolitan districts	(3 jobs) $9.01	(5 jobs) $8.87	.....	2%
Item 19: General expense. The amount charged to this miscellaneous item is expressed as a percentage of the total pay-roll.	1.8%	2.3%	.....	.....

Placing and Removing Floor Forms.—There is some difference in the cost per square foot for Item 3-F, as between flat slab and beam and girder construction. By a coincidence, it happens that 14% of the floor area in the percentage jobs was beam and girder and 86% was flat slab, while, in the lump-sum jobs, 13% was beam and girder and 87% was flat slab. Because of this similarity, the comparison made between the average units on the percentage work and on the lump-

sum work is not influenced by any difference due to the slightly greater cost of beam and girder forms over flat slab forms. The column spacing was sufficiently similar in all the buildings so that any difference due to this element may be disregarded. Item 3-F has a tendency to be lower in buildings having a greater number of stories, because the 3-F unit for the first floor is nearly always higher than the same units for the floors above that. As all the buildings studied are five or more stories in height, with the exception of two, which are four stories, the influence of the element of height is very slight. It is to be noted that the next to the lowest 3-F unit obtained on any of the 22 buildings was at Becker's Aniline and Chemical Building, which is only five stories high, and each of the units made on the two four-story jobs are below the average. It is believed that a comparison of the 3-F unit, as between the percentage group of jobs and the lump-sum group, is a fair one and means that, if anything, the organizations on the percentage "had the jump" on those on the lump-sum job for this item. Mr. Perry.

Mixing and Placing Concrete.—With equal efficiency on the two classes of construction, the averages of Item 22 should run very closely together, and such is the case, the difference being only 2%, in favor of the percentage organizations.

Receiving, Bending, Fabricating, and Placing Steel Reinforcement in Metropolitan Districts.—The lump-sum jobs exceeded the percentage jobs by 5%, and this difference is probably justified by the more difficult conditions affecting this Item 30, which existed on the percentage group of buildings.

Receiving, Bending, Fabricating, and Placing Steel Reinforcement on Jobs Outside of Metropolitan Districts.—The lump-sum jobs exceeded the percentage jobs by 2 per cent. The comparison is a fair one and should be a true indication of efficiency.

General Expense.—The amount of money covered by the classification in Item 19 is very small compared with the other items used in Table 1. The only reason for tabulating the item was to show by its smallness that improper charges had not been made to it, thereby reducing the charges of pay-roll made to Items 3-F, 22, and 30.

To some of the discussors, the results of this investigation made by the speaker's Company will sound like anarchy, but there is a sound reason back of these figures. It has been the experience of the Company that under a "cost plus" form of contract, there exists essentially a partnership between the owners and the contractor. There is only one interest, namely, to give the best work for the least money in the quickest time. If the contractor expects to continue in business, he has to earn the confidence and commendation of that particular owner. To lump-sum contractors there seems to be, in some cases, a

Mr. Perry.

different interest. Each side wants to be sure that the other side does not get the advantage under an agreed price.

Under "cost plus" contracts, the contractor feels free to go to the owner with suggestions for modified ways of doing the work, and for the substitution of methods or materials; and likewise the owner is more apt to give favorable consideration to the contractor's suggestions and to offer his co-operation and assistance in such matters as steam, light, power, railroad siding, supplies, purchasing, housing, and the like. Under a lump-sum contract, if the contractor comes to the owner with suggestions or requests, the owner is liable to say, "You have your lump-sum contract. Why should I help you out? I have no more interest than to see that I get what I want."

If, as is the case in nineteen out of twenty building contracts, changes, alterations, or additions are made in the work to be done after the contract is signed, the owner is at the mercy of the contractor on a lump-sum contract. We all know how difficult it is to put a contractor off the job, and how unusual it is to get another contractor to come in and do extra work when the first contractor is still on the job.

A friend of the speaker, a distinguished New England contractor, in the same line of business, puts this whole question in another, but particularly practical, way. His statement, as the speaker recalls it, was to the effect that he would like to see a comparison or a statement of the difference between the total cost paid by the owner for a given piece of work under a lump-sum contract when all extras had been paid for, and the cost of a similar piece of work done on a straight cost plus fee contract. It was his judgment that the average lump-sum contract plus extras, would cost the owner more than the "cost plus" or service form of contract.

The speaker would like to say just one word as to the recent vigorous condemnation of "cost plus" contracts. The question would seem to be not so much one of different types of contract as one of conditions under which work was done. It is hard to see any valid reason why labor should be less efficient on a percentage job than on a lump-sum job. A workman is naturally primarily interested in his own welfare and, therefore, in the keeping of his job. If negligence and a lack of interest in his work lead to his discharge on a percentage job just as quickly as on the lump-sum job, while he finds that diligence on the percentage job is awarded by advancement and continuous employment by the contractor, he will work just as hard on one form of contract as on another. The whole thing really comes down to the disposition, intent, and organization of the contractor.

There has been a pretty wide disposition to discredit "cost plus" contractors for the Government during the war and to blame the high costs of Army work on the "cost plus" contract. The speaker feels

that this is wrong. In the majority of cases the jobs were in out-of-the-way places, where it was extremely difficult to obtain labor, also at a time when there was a great demand for labor. Furthermore, the speaker feels that the war costs, high as they are known to be, resulted not only from the conditions mentioned, but also because of the inexperience of the workmen. The experienced workman in most lines of industry continued to give good services during the war when working for his old employer, but there were not nearly enough of these experienced workmen to carry on the Government building programme, and it was necessary, therefore, to employ large numbers of men new to the industry. These men were frequently found to be inefficient. Mr. Perry.

At present, the speaker's Company is erecting more than 50 buildings, practically all on a "cost plus" basis, and generally apparently to the owners' satisfaction. The owners on more than 200 other buildings, which the Company has built on "cost plus" contracts, seem to be satisfied with the costs, time, and quality of the work which they got. This is indicated by the surprisingly large number of repeat orders for buildings from "cost plus" clients. As a matter of fact, of a total volume of nearly $50 000 000 of private business, 72.2% has been on a repeat-order basis. This would seem to be a pretty good answer to the objections to "cost plus" contracts for private industrial business.

The Company kept a cost system regardless of the type of contract. The jobs are divided into some fifty odd accounting units, that is, detailed cost units, very much on the basis of manufacturing shop costs. The units under discussion are the pure net units without any respect to profit, overhead, insurance, or other general job or main office top charges. The costs quoted for lump-sum contracts are the net costs to the contractor. The contract price does not enter into the question. It is just as though one took the shop cost of making a wheel. This cost of that wheel would be presumably without any overhead expense; it would be merely the labor that went into the wheel, as distinct from the materials or the selling price. The Company sought to arrive at the unit costs.

To do building work economically, expeditiously, and well, in reinforced concrete, requires skill and complete organization and experience. Only contractors who can get work on a reasonable basis of compensation can retain organizations of this type. Many contractors can go in and gamble on their profits on a "hire-and-fire" basis, but the conservatively organized concern prefers not to take a chance on losing money, but to take only such work as gives a reasonable profit.

The figures quoted do not include the contractor's profit. They are merely unit costs or shop costs aside from insurance. The results, although for 1917 only, check very closely with 17 years' experience

Mr. Perry.

on more than 500 buildings. The Company has known for years that it got lower costs for the owner under a "cost plus" contract than it could for its own pocket-book on a lump-sum contract.

In reply to the question as to what is meant by "cost plus," whether it is cost plus percentage or cost plus a lump sum, the speaker would say that the 22 buildings under discussion were about equally divided, on the one hand, between the cost plus straight percentage on a sliding scale where the contractor's compensation varied directly as the cost of the work, and, on the other hand, a cost plus a fixed fee or lump sum, where the contractor's compensation was independent of the cost of the work. Some of these contracts had guaranteed totals with or without profit-sharing. There are many different ways of writing "cost plus" contracts; any one can sit down and work out twenty or more of them in an afternoon, but it is a fact that the best units, that is, the best net units of the cost of the work, have been made on unguaranteed jobs, and the reason for this is the spirit of confidence and co-operation which usually cannot be gotten from the owner under a lump-sum form of contract.

In regard to whether or not the lower cost of the "cost plus" contract in the speaker's organization was reflected in the amount that the owner had to pay for the job, or whether the Company made more money out of it, the speaker would say that if the contract was a straight unguaranteed cost plus percentage form, the cost paid by the owner is the net cost plus the fee, so that any variation in cost benefits the owner directly. If the contract has a guaranty or upset price, it usually also requires a profit-sharing clause, so that any lowering of unit net costs would benefit both the owner and the contractor. This profit sharing varies from one-half to one-third to the contractor and two-thirds to the owner. Occasionally, the owner's share is even higher.

On some of the Company's contracts it has profit-sharing, but not on a lump-sum contract. In this latter type, the contractor makes all the profits on any unexpended allowance that there may be. A "cost plus" contract with a guaranteed total is really an attempt on the owner's part to "eat his cake and keep it too." It is a cumbersome contract, because it is subject to all the careful estimating and bargaining on extras and credits that the lump-sum contract effects, and, at the same time, requires the minute cost keeping and negotiations with the owner which a "cost plus" job involves.

On every job the Company has, its superintendents' profit-sharing plan applies. In explanation of that plan, it may be stated that ever since 1910, the Company has been saying to the members of its construction organizations that if they equal or come inside of an agreed estimate, the superintendent, and on big jobs, his chief assistants, will get extra compensation or bonuses, varying by the amount that the estimate is exceeded. Recently, this plan has been extended to include the

principal foremen on every job. The speaker has mentioned an agreed estimate, and by this, he means that, on cost plus fee jobs, the estimate is submitted to the architect or engineer and the owner for their approval as a reasonable amount to allow for the work in the immediate control of the job organization. On lump-sum contracts, the estimate is not submitted to the architect, engineer, or owner. It has, however, on either kind of contract, to pass the profit-sharing committee of the Company. Mr. Perry.

On "cost plus" work the owner is told that any bonus earned under this plan is part of the cost of the work payable by him, because such bonus or extra compensation is, in a measure, extra salaries paid to the organization in order to get lower costs, and the owner benefits equally.

The statement has been frequently made that on "cost plus" work the men actually doing the work in the field know the character of contract, and the pocket of the disbursing agent, be it the Government or a private owner, suffers accordingly. The experience of the speaker's Company contradicts this, and it is believed that that experience has been sufficiently wide to make its opinion of fair value. As stated, the whole question is one of the spirit of the organization. If it is known throughout the rank and file of a contracting organization that a man is discharged just as quickly for careless shirking work or inefficiency on a "cost plus" job as he is on a lump-sum job, experience indicates that no difference can be detected in the unit costs between a "cost plus" or a lump-sum job. Unit costs really tell the story of the relative operation of the two contracts.

If there is efficient management, systematized inspection, and a determination to see that an organization is run on an even keel, regardless of the form of the contract, any difference in the unit cost on a job due to the form of contract would be in general in favor of the "cost plus" job.

Relative to the closeness of the two forms of contract in their comparative costs being due to the fact that the superintendents and the foremen shared in the profits, the speaker thinks that undoubtedly that is true, but it seems to him that if this point is admitted, it might be also admitted that the form of contract really makes no difference at all. The speaker recently made up some figures showing the difference between the estimates given by his Company to owners at the time of negotiating the contracts for their work and the actual costs which the same owners paid for the completed undertaking. These figures cover all "cost plus" contracts made between July, 1910, and January 1st, 1918, that is, about 7½ years, and cover about $12 500 000 worth of work. The actual cost paid by the owners, including all profits to the contractor and any bonuses to field organizations of the contractor, were less than the estimated costs by about

Mr. Perry. $400 000, or approximately 3 per cent. This covers a total of about 90 contracts for probably 115 buildings.

It would seem that this was a pretty good indication of the excellence of the management, the ability to estimate correctly the costs, and the consistent performance of the field organizations in carrying out the schedules set up for them. It checks back again to the proposition that the type of contract is not the determinate factor. The really important feature is the management and, perhaps, the intent and disposition of the contractor.

Mr. Seaman. HENRY B. SEAMAN,* M. AM. SOC. C. E.—In the discussion of this paper, reference has been made to Government work or, more properly speaking, to war work, and the apparently excessive cost of the "cost plus" contracts for the Government during the war. The cost of war work should never be compared with similar conditions on private work, as the cost of work for war purposes was of minor importance when compared with the time to be saved in its completion. There was an "enemy at the door", and an extra cost of, say, $1 000 000, on a large piece of work, was not to be compared with the possible saving of 2 weeks' time in its completion; not only were many lives in jeopardy, but victory itself was at stake.

At the beginning of the war, there was no time to enter into formal contracts. Contracts amounting to millions of dollars were awarded verbally, the terms to be confirmed in writing later, and the increasing number of contracts continually awarded gave no opportunity for details.

In due time, the various forms of contracts were fully considered by a board representing six different branches of the Government, and although the cost plus percentage form was considered the least desirable, it was found, for a considerable time, to be the only practicable form which could be adopted under the stress of circumstances. Later, however, modifications and improvements were introduced gradually and, in many instances, a bonus was offered to the contractor on any saving, under an agreed estimated cost.

The successful execution of a "cost plus" contract, whether on percentage or fixed fee, depends largely on the character of the chief contractor and his ability to control the execution of the work. Almost invariably his character will be found to pervade the entire work. It is for this reason that percentage work must be awarded by personal selection rather than by competition, and as personal selection may have the appearance of favoritism, it will be difficult to establish the practice on municipal or other public works.

* New York City.

FREDERICK GLAESER,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer is strongly imbued with the idea that the functions of the engineer do not end with the preparation of a set of specifications and drawings for a particular piece of work, but, like those of the sculptor, must include its completion, as created in his brain, even to the last detail of construction; he must not place on a second party, called a contractor, the responsibility for carrying out the plan. The thought which the writer desires to convey is that the middleman, as in merchandising, is a source of expense that possibly may be done away with in the future. This thought is highly important in these days of high prices, when expenses are pyramiding one on top of another, and the greatest opportunity for the engineer to do constructive service to-day lies, it is believed, in developing his executive powers, in order that he may be able to carry out properly a pre-arranged construction programme. Mr. Glaeser.

We all credit the contractor with the "know how", and, being in business to secure his living, he must earn it; but, because of the gamble that he must invariably take, he is bound to protect himself so that he will not lose. The natural thing, therefore, for him to do is, of course, to bid sufficiently safe so as not to pay for the privilege of doing the work. We have all had experience with various classes and types of men, and know that some must be watched more closely than others.

During the last two years, the writer has had opportunities to judge of the "cost plus" contract in its various phases, and is entirely in accord with, and a strong supporter of, the type. The forms used have included the "percentage fee" on a sliding scale; the "fixed fee" form, in which the fee was agreed on by both parties and usually was a certain percentage of the estimated cost agreed on by the owner and contractor before the work was begun; and, latterly, on small jobs, due to the fact that surplus materials were available, and because materials could be purchased at Government prices, the policy has been to assemble all the materials at a convenient storehouse or storage pile and ask for bids on furnishing the labor and equipment required to perform the work. This form of contract is limited in its application, necessarily, but has the advantage of employing the man who possesses the knowledge and experience, but lacks the capital. It has been proven to result in considerable economy. On work valued at approximately $100 000, made up of seventeen jobs, it has been possible, with a gang of general average characteristics, to save a considerable sum.

If it is necessary to enter into a contract, the ideal form, in the writer's opinion, and that which permits of more elasticity in its operation than those at present in vogue, is one in which the estimated

* Trenton, N. J.

Mr. Glaeser.

cost is agreed on, the fee fixed at a certain sum subject to adjustment in one of two ways, namely, a bonus if the actual cost is less than the estimated cost, and a penalty if the actual cost exceeds the estimated cost. It will be admitted that changes in plans may change considerably the cost of the work, but in that case the ingenuity and knowledge of the engineer is brought into play, adjustments are made on the basis of the original contract, and additions or subtractions are made from the sums involved. The tendency of this form of contract to make the parties thereto feel that a partnership exists, which can be beneficial to both, is an incentive with unlimited possibilities, and results in economy not otherwise obtainable.

In continuation of the idea expressed in one of the foregoing paragraphs, it would seem that one of the functions of a National Engineering Society would be the proper supervision of the execution of Federal, State, and Municipal undertakings of an engineering nature. It would seem that such a society, through its various local associations, could be so in touch with civic improvements as to bring about a considerable reduction in the cost of engineering works. This could be done by providing a clearing house through which the various services necessary for any piece of work could be supplied. Tools and equipment could be purchased or hired, and the middleman eliminated. Such a combination would give the engineer the opportunity to lessen the burden on the tax-payer, to reduce the cost of living very greatly, and to give a maximum of service to the community.

Mr. Snyder.

GEORGE D. SNYDER,* M. AM. SOC. C. E. (by letter).—There is one method of constructing engineering work that was not referred to in the paper and was only mentioned incidentally in the discussion, that is, where the engineer executes the work without the medium of a contractor, by employing labor and purchasing material, either in his own name or that of the owner, thereby becoming the owner's agent. By this means, instead of having three organizations to deal with—the owner's, the engineer's, and the contractor's—there are only two, the owner's and the engineer's.

When an engineer is retained to design and execute an engineering work, and the owner engages a contractor to do the actual construction, what he is really doing is employing a man who is skilled and experienced in the business of constructing to execute the plans and specifications of the engineer, whose remuneration is fixed in the contract whether it be a lump sum, by unit prices, or some form of "cost plus". In any case, he must produce a cheaper or better structure, or he must produce it in less time than it could be done without him, in order to justify his existence. In other words, he must effect sufficient saving to recompense himself, and, in addition, effect a saving

* New York City.

to the owner in money or time. As a matter of fact, on most works of the usual character, under stable conditions of prices of labor and material, the contractor does justify his existence. Mr. Snyder.

No general rule can be laid down as to which type of contract is preferable, as each has advantages under certain conditions.

The lump-sum form of contract is preferable where the character of the work is not unusual and where the quantities can be determined accurately in advance. It has the advantage to the owner of enabling him to figure with some accuracy, even allowing for a certain percentage of extras, on his probable capital outlay.

The unit price contract is preferable where the quantities cannot be determined accurately in advance.

The "cost plus" contract is more adapted to work where there is not sufficient time to work out full plans and specifications in advance, or where complete data as to the conditions to be met cannot be obtained.

The conditions adaptable to the work being done directly by the engineer are as follows, some of which however apply with equal force to the "cost plus" method:

1st.—Works of unprecedented character and difficulty.

2d.—Works where the time element is the ruling consideration and where there is not sufficient time available to work out completely and develop the plans and specifications before starting the work.

3d.—Works likely to extend over a long term of years during which marked changes in the prices of labor and materials and in the conditions under which the project is financed, may occur.

4th.—Works on which safety is the dominating consideration, where changes and alterations are to be made in a structure without discontinuing its use by the public.

Among works of unprecedented character and difficulty may be mentioned the completion of the Hudson River Tunnels of the Hudson and Manhattan Railroad. At the time work was resumed on these tunnels, the project had a bad financial history. The company had been in the hands of a receiver, and several contractors had been unable to complete the work. Therefore, when the owners invited bids to complete the project, such bids were so high that it was decided to reject them and execute the work at cost under the direction of the engineer. This was so successful that the entire system, with the exception of portions of the work on the land approaches, was done in this way.

The Hudson River Tunnels are also an illustration of the advantage of using this method where the time element is the ruling consideration, for if no work had been done until complete plans and specifications had been worked out, it would have delayed the ultimate com-

Mr. Snyder.

pletion very much. As it was, when the tunnels were partly completed, the management changed the plans in order to permit the use of multiple-unit trains instead of single-unit trolley cars, which was done without discontinuing any of the work in hand.

In regard to works extending over a long term of years, two instances may be mentioned, one having been done at cost by the engineer and the other by an ordinary unit-price contract. The financial panic of 1907 involved both owners so that they could not continue the work on account of their inability to get funds to meet bills and pay-rolls. In the first case, the construction of portions of the work was suspended without any legal or other difficulty, while, in the second case, a settlement had to be made with the contractor to compensate him for his loss due to the suspension of the work.

A case involving safety may be mentioned, namely, the alterations to the Center Street Loop to conform to the plans for the Dual Subway System after two of the tracks were in operation. In this case, a contract was let to the operating company to do the work at cost, and the work was executed under the direction of its engineers. It would have been very difficult to have drawn a contract that would have safeguarded the public and, at the same time, properly recompensed the contractor for the extra work necessary to do this under any other form of contract.

In doing work at cost, under the direction of the engineer, it is essential that he shall have the necessary experience and organization and that the necessary arrangements in regard to plant can be made. In cases where the plant is special, or where it will not have a longer life than that necessary to complete the work under consideration, it must be purchased and charged off to the work regardless of the character of the contract. Where the plant is very expensive in proportion to the cost of the work, and cannot be leased, it may be necessary to let the work to a contractor having a suitable plant.

To claim that the same efficiency of labor cannot be obtained on a cost job as on a contract job is an admission of inefficiency on the part of those directing the work. Of course, it is human nature for a contractor who has both contract and force account jobs under way, to assign his best men to the contract job; but there is no such incentive where the work is being done by the engineer directly as agent for the owner.

Doing work by the engineer without the medium of a contractor is applicable to public work, where State laws do not preclude such a method, but trouble may be had with labor owing to civil service requirements and rulings. Some of the Federal river and harbor work is executed by direct labor.

The advantages and disadvantages of these methods vary with the character of the work, the local and financial conditions, and the

owner's desires, and the engineer should not limit himself to any one method of executing his plans, but should freely use those best meeting the conditions. Mr. Snyder.

F. G. BAUM,* M. AM. SOC. C. E. (by letter).—The writer thinks that the "cost plus", or percentage, plan of doing construction work is an abomination and a practice which leads almost inevitably to loss of control of the cost of the work and loss of confidence of the owner in the engineer and contractor. Mr. Baum.

The contractor or engineer may be ever so honest, but the moment the men in his employ know the job is a percentage job, they think they are being loyal to their employer if they make all the "percentage" they can. This applies from the top down to the last laborer. The writer has heard the men (big and little) brag about how they "put it over" for the boss. Until human nature changes, the "cost plus" plan must lead to great dishonesty. The author admits:

"There can be, of course, great dishonesty under 'cost plus' contracts, but, if this occurs, it is the owner's fault in lax supervision of his own forces or from incompetent or dishonest engineers."

That is a remarkable statement. What control has the owner over the contractor's dishonesty or that of his men, or their competency?

The writer has always made it a practice to have nothing to do with the "cost plus" plan, except where no other course could be followed; and he thinks engineers, contractors, and architects, generally, will obtain a higher standing, if they abandon it entirely, except in emergency cases.

GEORGE PERRINE,† M. AM. SOC. C. E. (by letter).—"A contract is an agreement between two or more parties for the doing or the not doing of some definite thing."‡ Mr. Perrine.

In construction contracts the contractor agrees to do certain work and furnish the necessary materials for stated prices, for which he is to be paid by the owner. The prices are always stated in the contract, and the units for which these prices are to be paid can be accurately measured or counted.

For doing certain work described in the specifications, including the furnishing of all materials enumerated in the contract, the contractor expects just compensation (in addition to actual costs) for his services and experience, and the use of his organization, plant, and money in prosecuting the work.

The owner knows what the completed work will be worth to him; if it is a factory, it will give certain returns in rent, and so with other things, a value can be set on them. In order to fix the value, the owner

* San Francisco, Cal.

† New York City.

‡ "Contracts," by Parsons, Vol. I, p. 6.

Mr. Perrine.

engages an engineer or architect to make the estimates. If he is a good business man, he will engage an experienced adviser, as an insurance against serious mistakes in fixing the the value of his new property.

The owner has the estimate of his expert from which to judge the amount of capital involved; then he advertises for bids. Usually, such bids are called for as unit price or lump sum; in either case, the bid prices are to include the cost of the contractor's services and his profit. A number of contractors will bid, their bids varying more or less from the figures of the owner's expert. The expert can judge very closely from experience by comparison with the contractor's bids how much the contractor will probably realize for his services.

The contractor's first thought, when making up his bid, is: How much money has the owner appropriated to do the work? The next is: Who are to be my competitors? Then he bets a certain amount on his skill against that of the other contractors.

If the contractor's figures are much lower than those of the owner, the supposition is that he will lose money if awarded the contract and, therefore, trouble and disputes will arise between the contractor and the owner, which may be more expensive in the end than if a contract had been let to a reliable contractor at the owner's figures.

There are certain things for which the actual costs can be fixed before commencing construction. Quotations can be secured, good for a stated time, for materials and plant rental, these cost prices to hold good while a contractor is being selected.

After these provisional agreements are made, and a contractor is found who will be willing to do the work at the owner's estimated cost, the owner can decide whether or not he wants to build at the prevailing market prices. He then has his expert estimate the probable cost and fluctuation of the prices of labor, and the cost of labor and materials are added together to obtain the probable net cost of the work.

The owner knows what he can afford to pay for what he expects to get under the terms of the contract, but is often uncertain as to the personal ability and integrity of some of the contractors and their forces. If a contractor is losing money, the owner will probably have some difficulty and be put to additional expense to guard against getting poor material and workmanship.

It should be possible to guard against such conditions by letting a contract to one of several selected firms, the contract to cover the cost of the work based on the owner's estimate for the actual cost, including overhead expenses and the contractor's fee. The contractors who are invited to bid for the work should be required to divide their bids into three parts, net cost, overhead, and fee desired.

In order to give the contractor an incentive to save money, he should share with the owner any saving below the latter's estimated cost.

Mr. Perrine.

It is the duty of the owner's engineer to see that the contractor does not turn out poor work, in order to make a saving and, thereby, get an extra profit. It is also his duty to see that his inspectors' methods do not retard the contractor's forces.

The owner's engineer should add to his net cost the contractor's overhead charges and fee and a certain amount for contingencies. When the contractor signs the contract, he accepts the approved estimate of cost and contingencies as final and binding.

The contractors under consideration by the owner should be requested to examine the plans and make their own estimates, in order to decide whether they are willing to accept the contract based on the engineer's estimate.

If, in figuring the contractor's fee, the total cost of the contract should exceed the net cost plus, say, for example, 50% of the estimated contingencies, a deduction should be made in the contractor's percentage fee, by an amount in proportion to that which the cost exceeds the net cost, plus 50% of the contingencies. The object of this is to compel the contractor to exercise the best supervision in order to keep down the costs. By such a contract, the owner pays no more than his engineer estimates the cost to be, and the contractor has the opportunity of increasing his profit by exercising his skill. Orders for extras may be figured on the same basis as those for the general contract.

Mr. Reed.

P. L. Reed,* M. Am. Soc. C. E. (by letter).—When a prospective owner has decided to apply his funds to the construction of some structure or other engineering work, he may handle it in one or several ways:

(*a*) Employ the necessary foremen, mechanics, and laborers; purchase the necessary materials; and supervise the construction.

(*b*) Employ one or more superintendents on a salary basis and delegate to them the authority to hire some or all foremen, mechanics, and laborers; and to purchase some or all of the materials; and entrust to these superintendents the application of the labor and the materials.

(*c*) Employ a contractor on a "cost plus" basis and delegate to him most or all of the authority to employ labor, purchase materials, and apply them to the work to be accomplished.

(*d*) Enter into a fixed price or fixed unit price contract by which he delegates all authority for employment of labor, purchase of materials, and their respective applications.

Method (*a*) is "day labor" or "force account"; Method (*c*) is "cost plus"; Method (*b*) is an intermediate stage between Methods (*a*) and (*c*); and Method (*d*) is "contract" work.

* Washington, D. C.

Mr. Reed. It is to be noted that Methods (*a*), (*b*), (*c*), and (*d*) involve increasing delegation of authority, but that in Methods (*a*), (*b*), and (*c*), the owner retains the financial responsibility for results, and that only in Method (*d*) is he relieved of this. As Methods (*a*), (*b*), and (*c*) involve increasing delegation of power to spend without definite responsibility for costs, they imply increasing degrees of confidence or trust by the owner in his agents, coupled with financial supervision in different proportions according to circumstances. This element of trust which attains maximum proportions in the "cost plus" method of doing work is of so intangible a nature as to put this method under a great handicap in the award of public works, in normal times, and where competition is keen, even when permitted by law.

The author has suggested that "cost plus" contracts could be let on the basis of fee demanded, on the contractor's resources, and on his reputation. The only really tangible item in such a valuation of a competitive proposal would be the amount of the fee demanded, and to attach much weight to this item would be like selecting a doctor, a lawyer, or an engineer on a similar basis. The vital question is how well will he perform. The really important items are the intangible ones, and it must always be difficult, if not impossible, in normal times, to justify to the satisfaction of public bodies, awards of public works on such considerations.

The author explains the difficulty arising under fixed price contracts from extras, actual or alleged, which are largely avoided under "cost plus" contracts. On the other hand, the "cost plus" contract brings its own difficulties in the general control and auditing of the contractor's expenditures and in deciding what items are properly to be included in the cost of the work and what items are chargeable to the contractor's account, particularly as to items of indirect or overhead expense. Both kinds of difficulties, of course, are minimized by definite and complete plans and specifications in the case of the fixed price contract and a definite and comprehensive contract in the case of the "cost plus" contract.

In his advocacy of the "cost plus" method, the author suggests that the gamble belongs to the owner and mentions the uncertainties of site, weather, and varying market conditions; but what should be said about the gamble of competent and honest supervision and direction of purchases, plant, construction schedules, and organization and application of working forces? This latter part of the risk, and it is an exceedingly important part, belongs as logically to the contractor. If it be urged that the owner, himself, may supervise these things, then the contractor becomes little more than a salaried superintendent and we approach "day work" or "force account".

However, the gamble may be conceived to be divided in origin. It is within the power, and it is the practice, of the two contracting

parties to distribute it as they may agree. In some cases, the owner may be in a better position to assume the risks of the enterprise, in some cases the contractor; but, independent of this, one party may be more willing to assume risks than the other, and this will have a material effect on the form of the contract drawn to accomplish the "meeting of the minds". Mr. Reed.

The facilities of modern trade enable one to take risks or transfer them to others within a large range. A miller may buy his grain on the Exchange before it is harvested, for a definite price per bushel for future delivery, and we are told that various crops, such as fruit, are not infrequently sold by the producer for a definite lump sum on the trees, before they are ripe. We may carry insurance of many kinds to relieve ourselves to a large extent of various risks. An owner, either an individual, a private corporation, or a city, may have a sound reason for placing a contract for some improvement at a definite lump sum price, with the contractor assuming all risks. Nor does it follow that a fixed price contractor in assuming risks charges, in the long run, for contingencies which do not happen and that, on the whole, the owner pays more than he would had he assumed the risks. The contractor would naturally prefer to cover in his fixed price all possible contingencies, but if he did he would get little or no work in competition, and it is doubtful if, as a whole, contractors, in their estimates, do cover the contingencies which actually develop.

In manufacturing, the man in the shop may be paid by the hour or by the piece, with or without bonuses, premiums, or other elaborations. Both basic methods have been in use for many years, and there is yet no consensus of opinion as to which is the better. It is probable that each is to be preferred under certain conditions. Similarly, in contracting, the contractor, like the day worker, may be compensated by a fee, regardless of efficiency of performance, under a "cost plus" contract; or, like the piece worker, he may be paid a fixed price for accomplishing a definite result. In this case, too, the method to be preferred probably depends on the circumstances.

Recognizing that in the maximum delegation of authority to spend without definite responsibility for costs and incentive to economy lies the inherent defect in the "cost plus" contract, various modifications have been made in these contract forms.

The general types may be indicated as follows: (*a*) cost plus a percentage fee; (*b*) cost plus a percentage fee with a fixed maximum cost; (*c*) cost plus a percentage fee with a maximum fee; (*d*) cost plus a fixed fee, based on the estimated cost of the work; (*e*) cost plus a fixed fee with a bonus represented by a definite proportion of any savings effected in actual cost below the estimated cost. A limit may be set to the amount of the bonus; (*f*) cost plus a fixed fee with the bonus for saving as in (*e*) and a penalty repre-

Mr. Reed. sented by a definite proportion of any expenditure in excess of the estimated cost. A limit may be set to the amount of the penalty so as to leave a minimum fee.

It will be evident on consideration that Modifications (*b*), (*e*), and (*f*) of the simple "cost plus" forms are essentially compromises between the straight "cost plus" and the fixed price forms, and that they serve to divide the risks which the owner carries in a straight "cost plus" contract and which the contractor carries in a fixed price contract.

The exceptional conditions produced by the war had as elements: (*a*) The importance of a prompt commencement and vigorous prosecution of large and complicated projects of indefinite extent and detail, with economy a distinctly secondary consideration; (*b*) large, rapid, and uncertain fluctuations in prices of material and wages of labor; (*c*) serious disturbances in the normal operation of the law of supply and demand; (*d*) an exceptional degree of patriotic feeling which minimized fraud and induced impersonal devotion to the work.

These conditions were favorable to the "cost plus" method in the execution of public works. When a contractor is given a "cost plus" contract, he is essentially appointed to a position of trust, and the general power of committing the Government or a city to this relation is not one which the public will lightly place in the hands of its contracting officers in normal times.

Mr. Wheeler. WALTER H. WHEELER,* ASSOC. M. AM. SOC. C. E. (by letter).—The author sets forth in his paper certain advantages claimed for the "cost plus" contract over the "lump sum" or "item" form of contract, and invites discussion of the question.

There is little doubt that the majority of contractors favor "cost plus" contracts. On the other hand, it is the writer's belief that very few owners favor this form of contract, and there are certain good reasons why they should not, except on certain classes of work, such as repair work and excavation and grading where the kinds and quantities of materials are difficult to determine. The writer has been fortunate in his experience in being at various times a principal on construction in the capacity of engineer, contractor, and owner, and thus has had opportunity to observe and study contracts from these different viewpoints.

It seems clear that most of the advantages claimed for the "cost plus" contract vanish completely for most construction work, when the engineer who draws up the plans and specifications, performs his duty thoroughly, conscientiously, and intelligently.

One of the stock arguments which is often advanced by contractors in favor of the "cost plus" contract, is the time to be saved by letting the contract and starting the work before the plans and

* Minneapolis, Minn.

Mr. Wheeler.

specifications are complete. This is a very specious argument, and frequently owners are persuaded to let their contracts in this manner, cherishing the belief that time will be saved. Rarely is this expectation realized. On the contrary, the result is usually disappointing to the owner. Time usually is actually lost in straightening out the errors and mistakes that have been made in starting before everything had been worked out carefully on paper, and the cost, instead of being reduced, is increased, on account of the inability to organize the job properly for efficiency because of lack of knowledge of all the details of the work involved and through the errors previously mentioned. One reason why this argument of saving time is used so often by contractors who are after a certain piece of work, is obviously because they well know that after all the plans and specifications have been worked out, they will not have convincing arguments to present in favor of the "cost plus" contract. Certainly, no greater mistake can be made than to begin any undertaking, whether construction or other enterprise, without proper preparation, and proper preparation in a construction enterprise certainly involves complete plans and specifications.

In the absence of complete plans and specifications, the basis for a clean-cut contract is lacking. Under certain circumstances, haste in beginning work is sometimes justified, such as the necessity of retaining right-of-way rights, title, or some similar reason. However, it is not necessary as a rule to let a contract for more than a small part of the work in order to accomplish such a purpose, and the plans and specifications for the major work can be effected while the contracted portion is in progress.

It is the duty of the engineer to advise and even insist that his client have enough exploration work done to furnish reliable data on which to base his plans. Such work is usually relatively inexpensive and will frequently result in an entirely different plan being used. Often, in this way, many times the cost of the exploration work is saved. Engineering is or should be an exact science, and unless one has exact data on which to base plans and specifications, one is working on guesswork and not on fact.

It is argued that "cost plus" contracts save money for the owner. It is possible that such results are sometimes attained, or could be if plans and specifications were worked out with the same care and completeness under this system as they would be under the "lump sum" system. Here, in the writer's opinion, lies one of the dangers of the "cost plus" contract to the Engineering Profession. Regardless of how conscientious the engineer may be, he is almost certain to be less thorough in his work when he knows that there will be no "comeback" at him on account of extras resulting from his failure to have his plans and specifications complete, because it will simply be a

Mr. Wheeler.

matter of correcting the error or supplying the deficiency when discovered; but the cost is there just the same, although it may not appear as an "extra". The writer is very much inclined to be skeptical as to the saving that can be made on the cost.

Another argument advanced for the "cost plus" contract is the ease with which changes can be made as the work progresses, and one might get the impression from reading the paper that since these changes are easily or more easily made under the "cost plus" contract, they involve no additional cost because of the change. On the contrary, every contractor knows what it means to be making frequent changes in plans after work is started, or, worse yet, to be correcting or changing work which is already in place, and the greatly increased cost that results over what such cost would have been had the work been done that way in the beginning. Here, again, is another pitfall for owner and engineer. When the changes have to be taken up and their cost arrived at before they are made, as under the lump sum contract, the owner is impressed with such cost. Under the "cost plus" contract, the owner often does not awaken to a realization of the cost until the job is done and the final cost is known, and, in many instances, the job has not been finished, because adequate funds were not provided in the beginning to cover the total cost; or, if it is finished, it is a disappointment from an investment standpoint, as all the preliminary calculations are upset. Here, again, a heavy responsibility rests on the engineer to see that his client, and also that he, himself, studies the work so thoroughly and considers every detail so carefully while the plans are in preparation, that it will not be necessary to make changes after the contracts have been signed.

The writer cannot agree with Mr. Clarke's assertion that the "lump sum" contract has not the advantage of showing the cost of the work before starting, and that there is "invariably a long list of extras." If there is this "long list of extras", the writer would be inclined to place at least a part of the blame on the engineer who prepared the plans and specifications. He knows of considerable important work that has been carried through without, or practically without, a single extra. However, he sees no good reason why extras under the "lump sum" form of contract should be so difficult, provided a schedule of prices for extra work or deductions to cover contingencies is required of the contractor when the contracts are signed.

It is vitally important to the owner that he know very closely what the work will cost him before he awards the construction contract. There are many instances where owners have relied on the estimates of engineers or architects for the cost of the work or on the estimates made by contractors based on preliminary plans or sketches, with disastrous results. There are even instances where unsuspecting owners have been encouraged to go ahead with work,

usually on the "cost plus" system, by willfully misleading estimates, and, in some instances, have met with financial ruin as a result. In the writer's opinion, the engineer, architect, or contractor who so misleads an owner, either knowingly or through ignorance, should be severely punished under the law, and certainly this Society should not countenance anything of the kind and would not if the writer correctly understands its ideals. Mr. Wheeler.

The same principles will hold good on the argument that better workmanship is secured under the "cost plus" contract. It is simply a matter of making the plans and specifications clear and definite and seeing that they are followed, which would be just as necessary under the "cost plus" system. The writer can see no reason why the contractor bidding on a lump sum contract should have to "guess at" the meaning of the specifications. He has the privilege of making definite, by correspondence with the engineer, anything that is indefinite or difficult to interpret. If the plans and specifications are well drawn, why should there be anything in them that is indefinite? Is it not for the engineer to see that his plans and specifications are intelligible?

It would seem that for most work the "lump sum" form of contract comes nearest to meeting all the conditions and requirements of construction work in the best manner, and it is a matter of the engineer's ability, intelligence, and integrity to make it work out smoothly, fairly, and properly.

It is only fair to the contractor that he be protected against increases in wages, freight rates, and other contingencies such as strikes. As to material prices, he can secure protection for a long enough time to enable him to place his orders, and if he is negligent that is his lookout.

It seems to the writer that for public work the "lump sum" is much to be preferred to the "cost plus", as there are already too many opportunities for politics and "wire pulling" and these, in the writer's belief, would be increased by the adoption of the "cost plus" contract.

E. G. WALKER,* M. AM. SOC. C. E. (by letter).—An examination of this paper leaves the impression that its author is a strong advocate of the "cost plus" form of contract, almost to the exclusion of other forms. In his strong advocacy of it, he enumerates a number of points which he reads as great advantages of the system, but which to many other people would appeal rather as disadvantages. The whole question as to the best form of contract to be used for a particular job turns entirely on the circumstances under which the contract is being issued, and it is practically impossible to say that one form is better than another unless the particular circumstances of each case are taken fully into consideration. Mr. Walker.

* London, England.

Mr. Walker.

In general, in engineering practice, there are three parties primarily involved: (1) the owner; (2) the engineer; and (3) the contractor. The second and third parties have their status fairly closely defined, in that they are individuals or firms who specialize in their particular branches and are bound by the laws and customs of their respective professions. The owner, on the other hand, is drawn from the widest possible limits and may be a unit of any size, from a single individual to the whole nation. Further, he may be technical or non-technical, and the work which he is having done may or may not be embarked on for profit.

A still more important feature is that the nature of the work to be undertaken is in some circumstances definitely known before the contract is entered into. In other cases, it may be possible at best only to obtain an approximate idea beforehand of what has to be undertaken after the job has been started. To meet all these varying conditions and circumstances requires the development of several different types of contract. At the present time, conditions are probably much more favorable to the "cost plus" system than they are likely to be in more normal times, because, owing to shortage of materials and fluctuations of wages, it is difficult in many cases to get contractors to commit themselves definitely to prices for the necessary time ahead, which they have to do if they tender on the ordinary lump-sum basis.

The impression left by the author's case for the "cost plus" system is that when this system is developed to its utmost, the owner virtually becomes his own contractor, except that he hires the plant from the regular contractor and utilizes him as a kind of extended ganger over the working force. All responsibility as to the actual carrying out of the work is apparently to be left to the owner, who is also to shoulder all trouble that occurs with labor, and all risks, and to insure remuneration to the contractor no matter how the work may turn out. This seems to be rather an inversion of the ordinary notion. The writer believes that the generally accepted idea is that a contractor is paid and allowed to take profit on work mainly by reason of the fact that he is prepared to relieve the owner from the responsibilities of carrying out the work, and in the majority of cases it is believed that the principal advantage that owners see in putting work out to contract, is that their expenditure will be known beforehand within reasonable limits, and that the responsibility for the proper carrying out of the work will be largely taken off their shoulders and put on those of reputable specialists who are more competent to carry it than they are.

A point which the writer does not understand is that the author, in his concluding paragraphs, appears to imply that the "cost plus" system is eminently desirable for municipal work, although immediately before this he admits that this system allows of great dishonesty.

Mr. Walker.

The two statements appear to the writer to be incompatible, since it is self-evident that anything which allows of the development of greater dishonesty than the old system of contracts is hardly suitable for application to public bodies, in which, by the nature of their formation, the responsibility of the individual member is limited.

The writer believes that in general the standpoint to be adopted in deciding what type of contract shall be used in any particular case should be broadly that the job should be classified as either one of two types: (*a*) straightforward jobs, that is, jobs in which the amount of work to be done can be fairly closely estimated beforehand; and (*b*) uncertain jobs, that is, those in which this cannot be done. When the supply of material and labor is normal, jobs of the first class can be priced with a reasonable degree of accuracy, and for such work, in the majority of cases, it will probably be found that the owner prefers the old system of competitive tender, because his liability is fixed within moderately close limits thereby. In this class of job, alterations and additions to the original design are only small, and their value, therefore, will be only a small percentage of the original tender. With a priced schedule, the contractor does not stand a particularly abnormal chance of making a harvest on his extras, and even should his profit on them be at a greater rate than on the main contract, the actual money value is unlikely to be great enough to allow him to make an abnormal profit on the whole contract, and it is on the whole contract rather than on a few items in it that a true comparison should be based.

The second class of job is obviously the more difficult to deal with, and the two types of contract which can best be considered in connection with it, are the itemized schedule type and the "cost plus." It is probable that, in most instances, the "cost plus" will give the better results. In certain cases, it is evident that the owner must be prepared to face considerably more risk, and that his engineer must also be prepared to take more responsibility for the issue of technical instructions and orders in connection with the job. Furthermore, as the magnitude of the risk is uncertain before the job is started, it is obvious that a contractor is not in a position to estimate fairly what the work is worth to him and, therefore, must cover himself by a higher price. With the correlating circumstances that the owner is to take more risk, and the engineer more responsibility for technical supervision, a number of the disadvantages of the "cost plus" system referred to by the author are considerably reduced in importance. The writer believes that it is to this type of job that the "cost plus" system is more applicable, and he does not believe that it is a desirable system to use indiscriminately for all types of contract, and, in particular, he is of the opinion that considerable caution should be exercised in its application to cases in which public bodies are the owners.

Mr. Waddell.

J. A. L. WADDELL,* M. AM. SOC. C. E. (by letter).—The importance of the subject of this paper, to owners, contractors, and the entire American nation, cannot well be exaggerated; for, until there is reached a satisfactory compromise between owners on the one hand and contractors on the other concerning the vital questions of contract-letting and profit-sharing, the business of the country will fail to recuperate to the extent that it should at this critical period in the readjustment of all constructional activities—which activities were so fundamentally upset throughout the whole world more than five years ago by the advent of the World War. The opportunity now within easy reach of the American people to secure the bulk of the world's trade is unique; but, apparently, our leaders in diplomacy, manufacture, shipping, business, and finance are either unaware of its existence or indifferent about taking advantage of their good fortune. The Latin-American nations are now knocking at our door asking to do business with us and begging us to lend them money for the development of their as-yet-almost-virgin lands, mines, and water powers, and their other more or less embryonic resources; and the leading peoples of Asia, Africa, Australasia, and even Europe are to-day much more willing to enter into business relations with this country than they have ever been before. They all recognize that, for the present at least, the European countries are in no condition to lend money, being themselves borrowers and having so many demands at home for their time, attention, and capital that they are unable to pay attention to the needs of any nation but their own; and the entire civilized world is well aware of the fact that, in spite of our vast war debt, we are to-day the most wealthy of all peoples.

These conditions—unfortunately, as far as we are concerned—will not last indefinitely; and if we are so short-sighted as to neglect to seize the golden opportunity which is not only easily within our reach, but which is actually being tendered to us and almost forced on our acceptance, it will not be long before both England and Germany will re-secure the grip on the world's trade which they possessed in ante-bellum days.

Prevention of Progress.—One of the greatest stumbling blocks in the pathway of our nation's advancement is the conflict between labor and capital; and until it is removed the wheels of progress will be clogged, and the present paralyzation of all great peace industries will continue to exist—possibly in even worse form than it does to-day. Again, the main issues between labor and capital are these questions of contract-letting and profit-sharing. If they were once settled to the satisfaction of all concerned—bankers, manufacturers, contractors, and workmen—all other minor differences would quickly be adjusted. Such a settlement is perfectly feasible; and the possibility of its

* New York City.

speedy accomplishment is neither a Utopian conception nor an idle dream. Mr. Waddell.

Primarily, the men who do the work must have a substantial share in all net profits of manufacture and construction; but the way for them to obtain it is not by the organization of strikes nor by seizing the plant and running the business of the manufacturer or the contractor. The uneducated workman is no more fit to manage business and to handle industry than the sedentary office man is to undertake the physical labor of the workman—in fact, much less so; because it would generally be totally impracticable to educate the illiterate workman up to a state of efficiency which would enable him to undertake business management and finance, while, in most cases, in a comparatively short time, the office man's muscles could be developed sufficiently to enable him to endure the physical stress of the workman's job. Nothing of value can be accomplished by mob rule, as the pending subsidence of the present wave of Bolshevism will soon prove.

Labor and Capital.—Although it is certainly true that the laborer cannot succeed independently of the business man, it is equally true that the latter cannot accomplish much without the aid of the capitalist, hence it behooves business men and financiers to come quickly to a friendly understanding and agreement. In times past, the capitalist secured and exercised a strangle hold on the promoter, the manufacturer, and the contractor, often forcing them to turn over the lion's share of their profits as compensation for the use of money in the development of their undertakings; and these men in their turn endeavored to even up matters by getting their pound of flesh out of the workman by compelling him to labor long hours for meager compensation. To-day, the laboring man is beginning to come into his own; but if he unwisely takes too great advantage of his growing power, he will "kill the goose that lays the golden eggs", and this will ruin his chance of securing comfort and happiness for himself and his family.

The first step requisite for quieting the existing widely spread popular unrest and returning to normally prosperous conditions is to bring together, so that they may operate in harmony, the financier, the employer, and the laborer; and this must be accomplished primarily by establishing some method of contract-letting and profit-sharing which will be just and equitable to all parties interested. For some time, the writer has been endeavoring to formulate and develop, through communications to the technical press, an ideal method of accomplishing this desideratum; and later herein he will indicate clearly of what it consists. Meanwhile, he will discuss in detail not only the suggestions offered by Mr. Clarke in his timely paper, but also those of various engineers and political economists who have of late been treating the matter in print.

Mr. Waddell.

Various Methods of Contract-Letting.—The most common ways of contract-letting are the following:

A.—Lump sum for complete construction.

B.—Schedule rates for all materials in place.

C.—Actual cost plus a percentage, with some kind of allowance for overhead expenses.

D.—Actual cost of labor and materials plus a percentage, with no allowance for overhead expenses.

E.—Actual cost plus a lump sum, with some kind of allowance for overhead expenses.

F.—Actual cost of labor and materials plus a lump sum, with no allowance for overhead expenses.

G.—Actual cost plus a profit based on small unit prices agreed upon in the contract, as advocated of late by Mr. G. H. Hailey.

H.—Various methods of profit-sharing between the client and the contractor.

Method *A* generally appeals most of all to the client, because it fixes in advance what the construction is going to cost him, unless, perchance, there are important variations in the estimated total quantities of materials, due to lack of sufficient preliminary information or to the encountering of conditions that could not well have been foreseen. It is by no means as satisfactory to the contractor, however, who has to run the risk of being actually out of pocket on the job, in addition to the loss of personal time and effort.

Method *B* is quite an improvement on Method *A*, in that the contractor does not have to guarantee the correctness of the estimated quantities of materials; but the prime objection to Method *A* holds good for Method *B*, as the latter does not prevent the contractor from losing money heavily on the venture.

In the days of hard times, when contractors are willing to take work at low figures, and even below cost, in order to keep their force together, the public, in general, especially as represented by companies and municipalities, is prone to take advantage of them by insisting that work be let by the lump sum, and by throwing on the unfortunate "successful bidder" not only the risk of loss from rising prices of materials and labor and from unforeseen contingencies, but, also, in many cases, from excess of quantities above those given in the specifications. This is accomplished by inserting in the latter a most unjust clause compelling each bidder to verify for himself both the quantities stated and the character of the conditions described. The bidders, hungry for work, accept this clause without comment, but with the mental reservation that, in case of hard luck, they will, by some means or other, obtain extra compensation, even if they have to carry the controversy into the Courts.

Mr. Waddell.

In nineteen cases out of twenty, it is unjust to bidders to ask them to name a lump-sum compensation for doing work, unless provision is made for a variation in the quantities of materials on which they tender. If provision is arranged for such variation, the method of letting is no longer that of the "lump sum", but reduces to a modification of that of "unit prices".

As before indicated, the latter method is certainly the more logical, and yet it is far from being entirely fair to the contractor; because, although it provides against loss through excess above the estimated quantities of materials, it leaves him open to the possibility of still greater loss through changing prices, onerous unanticipated conditions, and disastrous happenings beyond his control. Up to a certain point, the client is the proper party to assume the principal risks inherent to the work, provided that the adverse happenings are really unavoidable by the contractor, and that the latter takes every reasonable precaution against disaster or loss. And yet the contractor should not be altogether relieved from the possibility of loss due to hard luck, because such misfortune is often caused by his dilatoriness, which carries the work into an unfavorable season for field operations. The idea, promulgated of late by certain writers, that it is unjust ever to penalize a contractor, is wrong; because he, like everybody else in this world, should bear the burden resulting from his own carelessness, negligence, or incompetence. The owner surely has some rights—and this is one of them. A liberal limit of total cost which can be increased or reduced properly, in order to provide for an increase or decrease in the estimated total quantities of materials, will prevent the owner from being excessively overcharged, and still will give the contractor every opportunity to come out whole in any case except that of extraordinary hard luck.

Method *C* is wholly objectionable to the client, in that it places him entirely at the mercy of the contractor and his men. The allowance for overhead may be either an assumed percentage, or the actually computed amount in complete detail, the former being generally the less objectionable. Even if the contractor is perfectly honest and has the best will in the world to keep down the cost for the benefit of the client, his employees will not have that desire. In effect, they say to themselves and to each other, "What is the use in my exerting myself unduly? The more the work costs, the more money the 'old man' makes". The writer knows this to be the case, for some years ago he had to let a large contract for foreign work at cost plus a percentage; and although the contractors themselves tried to do the honest thing at all times, their men "loafed" to such an extent that the final cost of the construction was atrociously high; and he had occasionally, on his own responsibility, to discharge some of the contractor's employees,

Mr. Waddell.

including once the field superintendent. This method of letting work involves asking too much of frail human nature.

Method *D* involves less labor in cost-keeping than Method *C*; but, otherwise, it is open to the same general objection.

Method *E* is almost as unsatisfactory to the client as Methods *C* and *D*, except that the contractor's reward for his own iniquity is a fixed quantity and not in direct proportion to the extent of that iniquity.

Method *F* involves a slight improvement on Method *E*, but only to the extent of a little simplification in bookkeeping and perhaps a reduced opportunity for "squeezing" the client.

The writer readily acknowledges that during war times, when the trend of the market for both materials and labor was rapidly upward, no contractor could have afforded to take work either for a lump sum or by unit prices. Unfortunately, in order to bring the war to a successful conclusion, a vast amount of public work had to be done with the utmost despatch, irrespective of what the cost might be; hence, the Government had no choice at all in the matter, and, consequently, it let many millions of dollars' worth of contracts at "cost plus a percentage" or "cost plus a lump sum". If the true history of all such contracts was ever written and made public, the nation would stand aghast at the extravagance they involved; and those two methods of contract-letting would receive the universal condemnation of all intelligent, disinterested persons.

As stated by one of the discussors, when a contractor has simultaneously two or more contracts, one of which is on the "cost plus" basis and the other or others on either the "lump-sum" or the "unit-price" basis, he will naturally put his best and most energetic men on the latter, and will shift the lazy and incompetent ones to the former. This practice has become so well established by custom that the "cost plus" contracts have been dubbed "hospital jobs"; and it appears that the nickname has stuck.

Is it not obvious that any one who lets a contract on the "cost plus" basis places himself absolutely at the mercy of the contractor and the contractor's employees? It is true that the specifications often contain restrictions which tend to lessen the contractor's power to take advantage of the client; but their enforcement would be very troublesome, and would generally involve litigation with its attendant delay and expense.

Most people will acknowledge that the percentage of truly conscientious contractors is not overwhelmingly large, but how much smaller is that of truly conscientious workmen! The writer does not deny that there are workmen who always give a *quid pro quo* and who are upright and honorable in all their dealings; but, alas, they are

Mr. Waddell.

sadly in the minority. Their number is so small that they are unable to induce their co-laborers to exert themselves any more than they are compelled to, unless they are paid by the job instead of by the day or hour.

By the way, when it is practicable, such a scheme of paying the workmen is an improvement on that of time compensation, because it provides a great incentive to effort; but, at the same time, it also serves as a strong temptation to scamp the work. With close supervision, however, and a strict enforcement of the clause in the specifications relating to the taking out and replacing of defectively built work, the employees soon learn, through the fines and penalties enforced by the contractor, that scamping does not pay, and that the old adage of honesty being the best policy is just as applicable now as it was when first enunciated.

Method *G* involves only a very slight modification of that of "cost plus a lump sum", the said lump sum being replaced by another sum obtained by adding together the products of the actual quantities of all the materials by certain small unit prices agreed on in the contract. Although the writer concedes that this method is undoubtedly the best of all the straight "cost plus" methods, it possesses all the serious objections inherent thereto.

In addition to those previously indicated, there might be mentioned the fact that any straight "cost plus" basis effectively cuts out competition, and advantages a favored few of the larger and more experienced contractors, rendering it difficult for the smaller and less experienced ones to secure any work, except through some other method of letting. It ought to be evident to any one possessed of ordinary vision that such a method will militate toward cutting the "small fry" contractors out of bidding; for when an owner is willing to let a piece of work on any straight "cost plus" basis, he naturally will want to award it to a large contractor of means, who has an established reputation for fairness and efficiency. That would practically mean letting all contract work without competition, and American contractors, as a body, would object seriously to any such procedure. It is true that the owner might call for competitive bids on the basis of having each bidder name a lump sum as a fixed net fee, and awarding the contract to the competitor who quotes the lowest figure; but the adoption of such a method would often result in serious trouble, delay, and expense.

Under the heading *H*, a number of profit-sharing methods have been tried and have proved to be more or less satisfactory. All of them necessarily presuppose a careful accounting of cost from start to finish. Unless the contract between the two parties clearly indicates how every main detail of cost is to be computed, there will be trouble before the work is finished. For instance, in respect to plant —does the contractor furnish it free of charge, or does he receive

Mr. Waddell

rental for it, with the rental charged as one of the items of cost of the work? How about paying for repairs and renewals to plant? Who stands the expense of these items—does the contractor, or is it charged as an item of cost of doing the work? Again, if extra work is done under the contract, how is it to be counted when making the final settlement?

It requires the service of an expert consulting engineer or that of an experienced contractor to draft a contract and specifications which will provide, in a manner satisfactory to both parties, for all possible contingencies. With such papers, however, and with a close system of cost-accounting, this general method of profit-sharing is the most satisfactory scheme for contract-letting, which can be evolved.

None of the modified methods of the "cost-plus" system, involving some means or other of profit-sharing, which has yet been tried in practice, can be said to be entirely satisfactory to the owner, though possibly so to the contractor, in that they all fail to put a limit on the total cost of the construction or to penalize a contractor who, through either wilfulness or carelessness, allows the cost of construction to pass the bounds of reason. It does not suffice to stipulate in the contract that, when the total cost passes a certain amount, the allowance for profit is gradually to be reduced until a certain minimum limit, however small it may be, is reached. The setting of that limit leaves the contractor in a position to take life easily and to avoid personal worry after his hard luck has attained to a certain magnitude; for, subsequently to that, he will lose nothing but his time and the possible use of his plant on some remunerative contract, while the owner will have to pay whatever additional amount the job may cost. On this point the writer knows whereof he speaks; because one of the war-time contracts engineered by his firm was, of necessity, let on that basis, and the results thereof are simply sickening. The client was left at the mercy of the contractor, and the total cost proved to be excessive.

From the preceding it is evident that the "cost-plus", the "lump-sum", and the "unit-price" methods of letting contracts are not only faulty, but also unjust to one or other of the two parties to the agreement; consequently, the question arises: "Is there not some method which will be just and fair to both?" That question, the writer claims, can truly be answered in the affirmative; but before proceeding to explain such a method in complete detail there will be presented a statement of the main requirements of an ideal system.

Salient Features of an Ideal System of Contract-Letting and Profit-Sharing.—The essential requirements of an ideal type of contract are as follows:

First.—It must provide a means of sharing with the workmen on an equitable basis the total net profit on the job.

Mr. Waddell.

Second.—It must set some kind of a limit to the total cost of the work, so as to prevent a careless or conscienceless contractor from running up the expense to an outrageously great amount.

Third.—It must reduce to a minimum the chance of the contractor's being out of pocket on the completion of the work, unless such condition is due to his own carelessness or lack of push.

Fourth.—It must retain all the advantages of competitive bidding, so as to give every capable and worthy contractor who is desirous of figuring on the work an even chance of securing the contract.

Fifth.—It must provide an incentive for the contractor and all his assistants and workmen to use every legitimate effort to make the work as inexpensive as possible, without violating in any manner the requirements of the specifications.

Sixth.—It must provide a just and equitable basis of payment for a possible increase in the estimate of total quantities and for adjusting satisfactorily to all concerned the reduction of payment due to a possible diminution thereof.

Seventh.—It must ensure that the owner will be acting for his own best interests by aiding the contractor in every possible way to complete his work quickly and inexpensively, provided, of course, that it is done in such a manner as to guarantee the attainment of the owner's ultimate purpose, as expressed in the specifications.

Eighth.—Its provisions must be such as to keep constantly in good humor every one connected with the construction.

Ninth.—Its method of final settlement of accounts must be clear, simple, and easy of application; and the keeping of them during the progress of the work must be no more complicated or expensive than it would be in the case of any ordinary "cost-plus" contract.

Description of the Ideal Method.—Let the specifications, which should invariably be drafted by an engineer who is acknowledged to be an expert in the class of work covered in the proposed contract, be complete and thorough in every detail, recording all that is known concerning the governing conditions; pointing out all features about which there is any uncertainty; tabulating as accurately as possible the estimated quantities of all the materials that will probably enter the construction; providing a justly drawn clause for unclassified work and the payment therefor; calling for each bidder to submit in full detail his estimate of actual cost of doing the work by applying to all quantities of materials given in the specifications, unit-cost prices

Mr. Waddell.

(termed Schedule A), each price containing a proportionate share of any contingency allowance that may have been made, totaling the products so as to form "Sum A", and adding thereto the amount of profit which he has decided to ask, thus making "Sum B". This last amount, in reality, will represent the bidder's tender; but to it, if it is accepted, there will be added a profit for the owner, exactly equal to that asked for by the successful bidder, and another profit or bonus for the employees, amounting to a previously fixed percentage (say, 20 or 25) of the sum of the aforesaid profits of the contractor and the owner, thus making "Sum C". This last sum is the temporary limit of total expenditure on the part of the owner, based on the assumption that the approximate quantities of materials given in the specifications are correct. The ratio r of "Sum C" to "Sum A" is to be applied to each of the unit prices used in the preparation of the cost estimate, in order to obtain the list of unit prices (termed "Schedule B") to apply temporarily to the actual quantities of materials in the completed construction, when making the final adjustment of accounts.

If there are any items of expense of construction not covered by the list given in the specifications, the clause of the latter relating to "Unclassified Work" will take care of them. That clause should stipulate that, for all such unlisted items, the actual cost of labor and materials therefor, without any allowance for superintendence or overhead, is to be recorded; and to it is to be added later 30% of its amount to allow for superintendence, overhead, and the various profits. This sum is to be added to the total value of the actual quantities of all the materials listed in the specifications figured at the proportionately increased unit prices as given in "Schedule B"; and the result, "Sum D" (with a single modification explained hereinafter), will be the final limiting cost to the owner and the basis for computing the net profits to be divided between the contractor, the owner, and the workmen.

The specifications, of course, will contain a clause providing a surety company bond for the faithful performance of the work and for guaranteeing the client against having to pay more than the limiting sum agreed on (as finally modified).

Method of Profit-Sharing Contract.—The following method of profit-sharing between the contractor, the owner, and the employees is to be adopted:

An accurate estimate of cost of every detail of the work from start to finish is to be kept by the contractor and verified by an accountant in the employ of the client, so that the total profit on the job may be ascertained by deducting this total cost from the maximum figure named in the contractor's tender and afterward embodied in the contract (modified, however, as hereinafter described). This profit, less

Mr. Waddell.

the amount of the employees' bonus, is to be shared between the contractor and the client as indicated in the profit diagram, Fig. 1. It should be clearly understood that every direct and indirect expense to which the contractor is put in doing the work, after the contract is signed, is to be included in the cost—all overhead expenses of every kind, plant deterioration, traveling expenses, supervision, and salaries, excepting only that the contractor himself is not entitled to any salary. In the case of a firm being the contractor, the head of that firm should receive no salary; but if any of the juniors devote their time exclusively to the job, it would be legitimate to allow them reasonable salaries, equivalent to what would have to be paid to regular assistants. All such matters, however, should be stipulated in the contract.

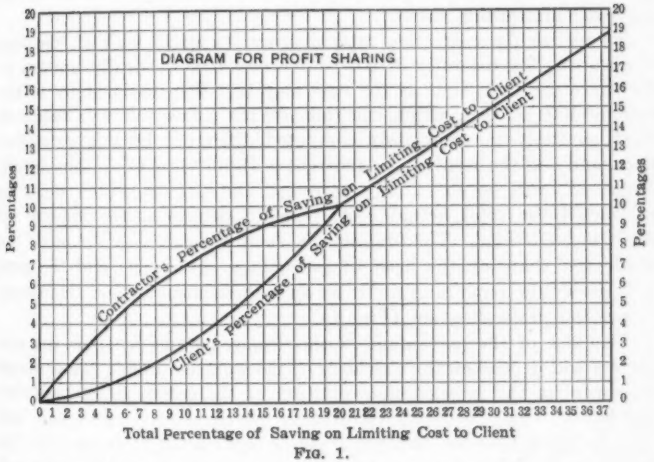

FIG. 1.

In order to determine, after the entire job is finished, the amount due the contractor, "Sum C" is to be subtracted from "Sum D", and the ratio which this difference (either a positive or a negative quantity) bears to "Sum C" is to be figured and adopted in the use of the diagram of "corrective ratios" (Fig. 2) for the said difference.

Application of Corrective Ratio.—There are two reasons for applying this corrective ratio;

First.—In the case where the actual quantities of materials exceed the estimated ones of the specifications, it would be hardly fair to the owner to apply to the excess those unit prices which produce his tentative limiting expenditure.

Second.—In the case where the actual quantities of materials are less than the estimated ones, it would be unjust to the contractor to

Mr. Waddell.

use the high unit prices on the diminution quantities, not only because of the great difference between these and the unit actual costs, but, also, for the reason that the total overhead charges would be about the same for the diminished amounts as for the estimated total quantities.

In the corrective ratio diagram (Fig. 2), it will be noticed, that, after the ratio of value difference (due to increase or diminution of quantities of materials) reaches 0.2, the "corrective ratio" remains constant at 0.8, which corresponds approximately to actual cost conditions. The object of this is to provide that the contractor shall not be too much benefited by an abnormal increase in quantities, nor, on the other hand, shall he obtain too much advantage because of an abnormal diminution thereof.

To utilize the corrective ratio diagram (Fig. 2), look on the line of abscissas for the ratio of cost difference, pass vertically upward to the curve (or right line, as the case may be,) then horizontally to the extreme left vertical, which will indicate the corrective ratio required. Next, multiply the previously computed difference by this corrective ratio, and add the result to or subtract it from "Sum C". The result, "Sum E", will be the finally corrected limit, from which must be subtracted the total actual cost so as to determine the amount of profit to be divided. The first step in such division is to set aside the employees' share on the basis of percentage agreed on; and the next is to divide the remaining profit between the contractor and the owner, as per the profit diagram (Fig. 1).

The size of the percentage of the declared profit to allow the employees will depend on the character of the work covered in the contract in respect to the proportionate division of the cost between materials and labor. Under ordinary conditions, the division is about half and half, in which case the employees' percentage should be from 20 to 25; but where the labor cost preponderates these figures should be increased, and where the materials cost is the greater they should be diminished.

In respect to the division of this bonus among the employees, the following method is suggested:

Only those workmen or assistants of any class who have stayed on the job, either until its completion or until their services were no longer needed, should participate in the profits; and the amount of the share of each such workman and assistant should be in the proportion which his total earnings on the work bears to the grand total of the earnings of all those employees who so participate. As, in any good business organization, a record is always kept of the amount of salary or wages paid to each employee on any contract, it would require only a few hours of extra work for the bookkeeper, after the job is finished, to compute each man's proportionate share of the bonus.

Mr. Waddell.

There is an additional protection against possible loss which might be given to the contractor under certain conditions, especially on work to be done in a foreign country. If it be anticipated that during construction any large general rise in the price of labor is likely to occur, thus greatly augmenting the total cost of the work, the limiting total expenditure of the owner, as hereinbefore finally adjusted, should be increased by an amount figured thus:

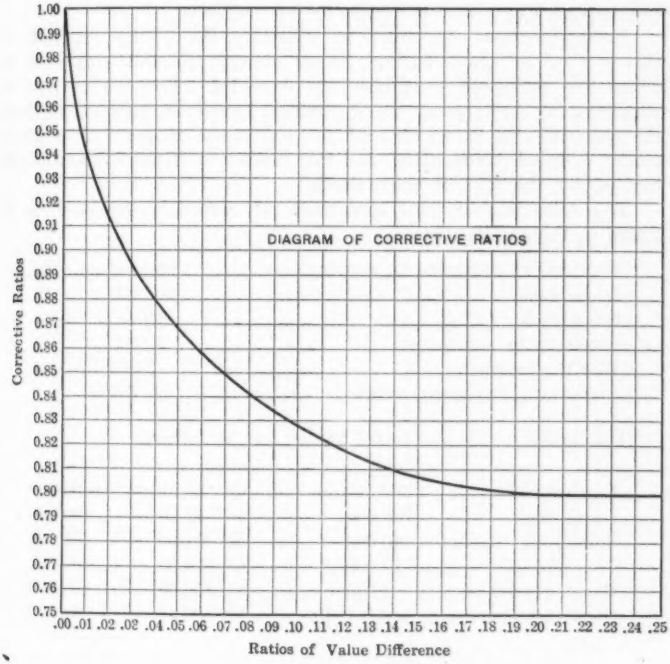

FIG. 2.

Determine the average current wages for common labor at the time of letting the contract, and the average paid therefor during the entire time occupied by the construction, and call the ratio of these two averages r'; then figure the total amount of salaries and wages paid to employees from start to finish and call it W. Then,

$$W\ (r' - 1) \times 1.2$$

will be the amount required, the factor, 1.2, covering a fair allowance for overhead and profits.

Mr. Waddell.

It has been suggested of late in the technical press that the contractor himself should be paid a salary by the owner, in addition to whatever profit he may make on the job. Such a policy would be simply suicidal on the part of the owner, for if the work were to be handled badly, the contractor might continue to earn money while the owner would be losing heavily. The writer has met with just such a case; hence, in this particular, he certainly knows whereof he speaks. Such a practice should never, under any conditions, be countenanced by either the owner or his engineer.

Exemplification.—In order to illustrate the *modus operandi* of this method of profit-sharing, let us assume the following case, in which the estimated quantities are exceeded. For the purpose of simplification in figuring, round numbers have been assumed for both the quantities of materials and the unit costs thereof. The job is one of railroad construction, and the number of items is intentionally limited for the sake of convenience.

The following are the quantities of materials supposed to be stated in the specifications:

Earthwork, measured in cutting.....	1 000 000 cu. yd.
Loose rock, " " "	100 000 " "
Solid rock, " " "	40 000 " "
Concrete in structures.....	10 000 " "
Wooden trestle	2 000 lin. ft.
Structural steelwork, erected.....	500 000 lb.

The tender of the successful bidder was as follows:

	Quantities.	Schedule A.	Totals.
Earthwork	1 000 000 cu. yd.	@ $0.50 =	$500 000
Loose rock.....	100 000 " "	@ $1.00 =	100 000
Solid rock	40 000 " "	@ $1.50 =	60 000
Concrete	10 000 " "	@ $20.00 =	200 000
Wooden trestle..	2 000 lin. ft.	@ $50.00 =	100 000
Steelwork	500 000 lb.	@ $0.08 =	40 000
Total estimated cost ("Sum A") =			$1 000 000
Profit required, 10% =			100 000
Tender ("Sum B") =			$1 100 000
Allowance for owner's profit =			100 000
Employees' profit, 25% of $200 000 =			50 000
Temporary limit ("Sum C") =			$1 250 000

$$\text{Ratio, } r = \frac{\text{Sum } C}{\text{Sum } A} = \frac{\$1\,250\,000}{\$1\,000\,000} = 1.25.$$

Mr. Waddell.

The proportionately increased unit prices, therefore, will be as follows:

Schedule B.

Earthwork	$0.50	× 1.25 =	$0.625
Loose rock	$1.00	× 1.25 =	$1.25
Solid rock	$1.50	× 1.25 =	$1.875
Concrete	$20.00	× 1.25 =	$25.00
Wooden trestle	$50.00	× 1.25 =	$62.50
Steelwork	$0.08	× 1.25 =	$0.10

The actual quantities of the materials in the completed job were, as follows:

Earthwork	980 000 cu. yd.
Loose rock	110 000 " "
Solid rock	50 000 " "
Concrete	10 500 " "
Wooden trestle	2 100 lin. ft.
Steelwork	480 000 lb.

In addition, there was done by the contractor certain "unclassified work" which actually cost him for labor and materials $20 000.

The revised estimate is, therefore, as follows:

Earthwork	980 000 cu. yd.	@	$0.625 =	$612 500
Loose rock	110 000 " "	@	$1.25 =	137 500
Solid rock	50 000 " "	@	$1.875 =	93 750
Concrete	10 500 " "	@	$25.00 =	262 500
Wooden trestle	2 100 lin. ft.	@	$62.50 =	131 250
Steelwork	480 000 lb.	@	$0.10 =	48 000
Unclassified work	$20 000 × 1.3 =			26 000
Summation, or "Sum D"			=	$1 311 500

The difference between "Sum D" and "Sum C" equals

$$\$1\,311\,500 - \$1\,250\,000 = \$61\,500.$$

$$\text{Ratio of difference} = \frac{\$61\,500}{\$1\,250\,000} = 0.0492;\ \text{say, } 0.05.$$

For this ratio, the diagram, Fig. 2, gives a corrective ratio of 0.865, which multiplied by $61 500 gives $53 198, say, $53 200, making the corrected limit, or "Sum E", = $1 250 000 + $53 200 = $1 303 200.

If the total actual cost of the work, including that of the unclassified work without allowance for superintendence or overhead, amounted to $1 100 000, the total profit would be:

$$\$1\,303\,200 - \$1\,100\,000 = \$203\,200.$$

Mr. Waddell.

Of this, the joint share of the contractor and the owner would be:

$$\$203\,200 \div 1.25 = \$162\,560;$$

and the employees' bonus would be:

$$\$203\,200 - \$162\,560 = \$40\,640,$$

which is exactly 25% of $162 560.

In respect to the division of this last amount between the contractor and the owner, its ratio to total cost is:

$$\$162\,560 \div \$1\,100\,000 = 0.148, \text{ or } 14.8\%.$$

From the diagram for profit division (Fig. 1), we find the division of this percentage to be:

Contractor	8.9%
Owner	5.9%

This makes the total payment by the owner to the contractor:

$$\$1\,100\,000 \times 108.9 = \$1\,197\,900$$

Let us now take a case where there is a diminution in the estimated quantities of materials. Using the same case as before in respect to estimated quantities and tender, we shall assume the following actual quantities of materials:

Earthwork	1 050 000 cu. yd.
Loose rock	50 000 " "
Solid rock.....	20 000 " "
Concrete	8 000 " "
Wooden trestle.....	1 800 lin. ft.
Steel work.....	450 000 lb.

The cost of the unclassified work was $20 000, as in the preceding case.

The revised estimate is, therefore, as follows:

Earthwork	1 050 000 cu. yd.	@	$0.625 =	$656 250
Loose rock.....	50 000 " "	@	$1.25 =	62 500
Solid rock.....	20 000 " "	@	$1.875 =	37 500
Concrete	8 000 " "	@	$25.00 =	200 000
Wooden trestle..	1 800 lin. ft.	@	$62.50 =	112 500
Steelwork	450 000 lb.	@	$0.10 =	45 000
Unclassified work.....	$20 000 × 1.3 =			26 000
Summation, or "Sum D".....			=	$1 139 750

The difference between "Sum D" and "Sum C" equals

$$\$1\,139\,750 - \$1\,250\,000 = -\$110\,250$$

$$\text{Ratio of difference} = \frac{\$110\,250}{\$1\,250\,000} = 0.0882$$

Mr. Waddell.

For this ratio, the diagram gives a corrective ratio of 0.835, which, multiplied by $110 250, gives $92 059, say, $92 100, making the corrected limit,

$$\text{"Sum E"} = \$1\,250\,000 - \$92\,100 = \$1\,157\,900.$$

If the total actual cost of the construction, including that of the unclassified work without allowance for superintendence or overhead, amounted to $880 000, the total profit would be:

$$\$1\,157\,900 - \$880\,000 = \$277\,900.$$

Of this, the joint share of the contractor and the owner would be:

$$\$277\,900 \div 1.25 = \$222\,320,$$

and the employees' bonus would be:

$$\$277\,900 - \$222\,320 = \$55\,580,$$

which is exactly 25% of $222 320.

In respect to the division of this last amount between the contractor and the owner, its ratio to total cost is:

$$\$222\,320 \div \$880\,000 = 0.253, \text{ or } 25.3\%.$$

From the diagram for profit division, (Fig. 1), we find the division of this percentage to be on the "fifty-fifty" basis, making the total payment by the owner to the contractor $= \$880\,000 \times 1.1265 = \$991\,320$.

Advantages.—The advantages of this method of contract-letting are as follows:

First.—While it is true that the client at the outset does not know exactly what the work is going to cost him, he is positive that it will not cost him materially more than a certain amount, provided his engineer's estimate of quantities is about right, as, generally speaking, it certainly ought to be.

Second.—The client has the satisfaction of feeling that even if, in his opinion, the limit determined by the contractor's bid is excessive, and that the final net profit on the job, in consequence, will be too large, the said net profit will be shared between them on a "fifty-fifty" basis.

Third.—While the client is bound to pay a certain percentage of the joint profit as a bonus to the contract's employees, generally he will not be out of pocket thereby, but, on the contrary, he will gain; because the incentive that the prospective bonus gives to all hands to labor energetically will save in the total cost much more than the amount of the bonus.

Fourth.—All the advantages of competitive bidding are retained by this method, because the fully capable competitor who tenders the

Mr. Waddell.

lowest amount for "Sum B" should be awarded the contract. All bids will be on exactly the same basis, no modification of the stipulated method of tendering being permitted. It is understood, of course, that the contract will not be awarded to any competitor who does not possess the necessary experience, capital, and plant, and who has not an established reputation for doing good and satisfactory work.

Fifth.—The contractor, if he was not too keen in bidding, knows that there is almost no chance whatsoever of his losing money on the job; because before doing so he would have to use up his allowance for contingencies, his own estimated profit, a profit of like amount allowed for the owner, and a substantial sum representing the employees' bonus. If he ever does use up all these safeguards, the chances are many to one that the fault therefor is entirely his own, being due to his negligence, lack of forethought, or deficiency in energy and push; and in that event he certainly would deserve to be penalized.

Sixth.—All the workmen and salaried employees of the contractor will be satisfied with their job because of the excellent opportunity offered for extra compensation; and they will, of their own accord, work diligently, and occasionally even overtime, in order to expedite the construction. Of their own accord, too, they will run off the job any employee who is a chronic shirker, and they will make it their business to keep everybody busy; because the more cheaply the construction is done the greater will be the bonus to divide among the faithful employees who stick by the work to the finish.

Seventh.—The method of profit-sharing given by the diagram for profit division (Fig. 1), is eminently equitable, in that when the net amount is small, nearly all of it goes to the contractor, and, as it augments, a continually increasing proportion of it goes to the owner, up to the point where the total joint profit amounts to 20%, after which the partition is on a "fifty-fifty" basis.

It will be seen that for a total net joint profit of less than 20%, the following divisions will prevail:

With 5% net, 4% goes to the contractor and 1% to the owner
With 10% net, 7% " " " " " 3% " " "
With 15% net, 9% " " " " " 6% " " " .

The 20% point was selected for equal division as being the one above which a contract is generally deemed by contractors to be good, slightly below which it is only fair, and much below which it is bad; for it corresponds to a net profit of 10 per cent. That is as small a margin as is generally deemed safe for any bidder to tender upon, and yet it constitutes a satisfactory profit on a finished job. As for limiting the client's share of the profit to one-half—that is rea-

sonable and just, because he would have no moral right to receive more than his partner, the contractor. If the client's share were allowed to increase indefinitely, it is conceivable that, with a very large prospective total profit, the contractor could save money for himself by making the work more expensive. Mr. Waddell.

Any bidder who tenders on the basis of a profit of less than 10% should be looked on askance by the owner and his engineer; and such a competitor should not be awarded the contract, unless he possesses an exceptionally fine reputation for doing good work and for not quitting his job before finishing it. It is true that during very hard times many worthy contractors are willing to work almost for actual cost, in order to keep their workmen employed; and in such cases the good intention should be recognized in making the award. Nevertheless, it nearly always proves to be unsatisfactory to both the owner and his engineer to let a contract for any piece of construction at a figure below its real value.

Eighth.—The contractor will feel during the progress of the construction that the client is a partner on the job, and that, therefore, he and his engineers will not be likely to be unnecessarily severe in their requirements, also that they will permit the adoption of all legitimate expense-saving expedients, and will not demand too many frills on the finishing.

Ninth.—Owing to the justice and equity involved by this method of contract-letting and profit-sharing, all concerned in the execution of the work will labor whole-heartedly and good-naturedly, avoiding petty squabbles and disagreements; and the result will be earnest, honest effort, a satisfactory piece of construction, and the general contentment of both parties to the agreement.

Tenth.—While this method may have at first glance the appearance of being complicated, it is quite simple; and because of the clear manner in which it is explained herein, it is easily utilized in any actual case by following one step at a time the directions given. The nomenclature of "sums" and "schedules" renders the application of the method very easy. Moreover, it must be remembered that it is to be used only once for each contract, and then only after all the work is completed and the accounts are in proper form. Again, the keeping of the accounts is in no way any more complicated than it would be in case any of the "cost plus" methods were used.

Objections That Have Been Raised to This Method.—A few objections, both orally and in print, have been raised to this proposed method of contract-letting and profit-sharing; but they could not have been well considered, for they are not valid. It will be well before closing this discussion to mention them and show wherein they are untenable. They are as follows:

Mr. Waddell.

A.—It has been asserted that there would be special difficulty in keeping the accounts; but there would be required therefor exactly the same work which would be necessitated by any of the "cost plus" methods. They all involve a correct record of the amount of every legitimate item of expense to which the contractor is put; and the bookkeeping in any case would certainly require an account with each employee, so as to show how much money had been paid him from start to finish.

B.—It has been claimed that the method is too complicated to be useful. On the contrary, as explained previously, it is simple; and the peculiar manner of its presentation herein is such as to render its use merely a matter of following step by step certain clearly written instructions. Moreover, as before indicated, this method of settlement of accounts is used only once, *viz.*, after the completion of the job.

C.—It has been stated that uneducated contractors would have difficulty in understanding the method; but the man who made this claim did the average American contractor a grave injustice. The construction contractors in this country are as bright a body of men as one can find anywhere; and certainly they may be trusted to understand anything in reason that affects their interests.

D.—It has been claimed that most contractors have a general inherent objection to sharing profits with the owner; but a little consideration will show that there is no sharing of the requested profit until after the estimated cost of the work (under the assumption of unchanged quantities of materials) has been exceeded. It was to clarify this situation that the writer changed his original idea of having each bidder name a lump sum (corresponding to "Sum C") as a provisional limit of the owner's total expenditure, and a list of unit prices (corresponding to "Schedule B") which, when applied to the estimated quantities of the specifications, would make the sum of the products exactly equal to the said lump sum, and substituted therefor the method herein described, *viz.*, that of having each bidder submit in detail his estimate of cost and his desired profit, so as to base the competition on the sums thereof thus tendered, and arranging the method of determining the limiting cost to the owner by two additions to the successful bidder's total tender. This change is simply a concession to prejudice, and does not modify the method proposed by the writer in his letter published in *Contracting* in its issue of September 15th, 1919. The only fundamental change between that presentation of the matter and this one is the inclusion herein of a bonus for the employees.

E.—It has been claimed that this method would tend to deceive the owner. He would certainly be stupid if he could not see clearly how its tendency is to cut down the amount that he will pay

for the entire work, and that it will set a just limit beyond which, under the worst possible conditions, he cannot be compelled to pay any more. Mr. Waddell.

F.—It has been stated, as a reason for favoring the "cost plus" system, that bonding companies favor it and oppose all other methods of contract-letting. Naturally, they would do so; because, with the "cost plus" method, their obligation reduces almost to zero, the risk being placed solely on the owner. In truth, with that method adopted, there does not appear to be any valid reason for having a bond at all. When the contractor runs no risk of loss whatsoever, why a surety company bond? Possibly, if the surety companies would consider it from this point of view, they would not oppose the writer's suggested method of contract-letting; for, while it reduces very greatly the possibility of loss to the surety company, it does not destroy that organization's function by removing entirely its *raison d'être.*

G.—The claim has been made that this method is not applicable to cases where no estimate of quantities has been made or for which no specifications have been prepared, and when it is necessary to let the work without delay. The correctness of this claim is granted, but its applicability should be confined to war work, in which the element of time is the principal consideration. In civil life, if a projector of an enterprise is in such haste to start his work that he has to omit the preparation of specifications and estimates of quantities before letting the contract, he certainly deserves what is coming to him in case it proves that he has placed himself in the hands of an unscrupulous contractor on the "cost plus" basis.

H.—It has been pointed out that the law will prevent certain public bodies from letting contracts on a "cost plus" basis, and that such a ruling might apply to the writer's proposed method also. If such really is the case, the remedy would evidently be to modify the law so as to permit of its adoption; but would not the fact of its containing a clause which sets a limit to the contractor's total compensation always render the method legal? This, however, is a question for the lawyers to settle.

I.—A prominent writer on economics has lately issued a tirade against gambling, especially as it applies to contractors guaranteeing owners against the cost of work exceeding the amount of the tender. The writer concurs in this theory to the extent that there should be no gambling on the amounts of assumed quantities of materials, or, in certain cases, on there not being any great rise in the average price of labor, or on possible loss through any reasonably great amount of hard luck; but there is certainly nothing unmoral or oppressive in insisting on his gambling to the extent of guaranteeing against his own incompetency, carelessness, or lack of forethought. The writer is of the opinion that a margin against actual money loss to the contractor, consisting of his estimated amount for contingencies, plus

Mr. Waddell.

his requested profit, plus an equal profit for the owner, plus a substantial bonus for the employees, is amply large to guarantee him against all loss through ordinarily unfavorable eventualities; and that, in ninety-nine cases out of a hundred, if such a margin were exceeded, it would be because of the contractor's own fault.

Adoption of Method.—If this proposed method of contract-letting and profit-sharing is received with favor by engineers, architects, contractors, and builders in general, it could easily be adopted as a standard for the country by calling a small convention with a single representative from each of the leading technical and railroad societies, contracting organizations, bankers' associations, and labor guilds, to discuss the advisability of adopting it (or else some modification of it) and to report the decision of the meeting to the said bodies for their approval. If any large group of clients, such as the railroad companies, were to adopt the method as standard and use it, very soon everybody having construction contracts to let would follow their example, thus making it the universal standard of contract-letting for the country—nor would it be long before other American countries would follow our lead, thus greatly simplifying our business relations with the various American Commonwealths.

Addendum.—In all lines of manufacture the employees should share in the net annual profits of the company; but, in figuring the yearly cost of running the establishment and doing the work, there should be included fair salaries for all the working officers, 6% on the actual amount of cash invested in the plant and business (but not on the total capital stock), an annual allowance for a sinking fund to redeem the bonds or other indebtedness of the organization, and taxes of every kind. The net profit estimated in this way should generally be divided on the basis of one-third to the employees and two-thirds to the company, but sometimes, perhaps, on that of one-fourth and three-fourths. The reason why it should not be split on a "fifty-fifty" basis is that the company has to run the risk of standing a loss in bad years, while the employees do not. Only those employees who are still connected with the company at the end of the year, or who have been discharged in good standing, should share in the bonus; and their proportionate amounts should be computed as previously indicated for the case of construction contracts.

Mr. Woolley.

WILLIAM E. WOOLLEY,* ASSOC. M. AM. SOC. C. E. (by letter).—On reading Mr. Clarke's paper, one concludes that he is an advocate of the "cost plus" system. The writer, however, cannot conceive the idea that the system will ever come into general use.

An owner who intends to build naturally desires to know what he will have to pay, and when he may expect the work to be completed.

* London, England.

Mr. Woolley.

One can say, in fact, that the first question asked is, "How much will the job cost?" How is the engineer to answer when the "cost plus" system is to be adopted? Under the older forms of contract, engineers and architects have been able in the past to answer these two questions fairly accurately, but now, owing to the constantly increasing cost of materials and labor, and the unsettled state of the labor market, we have made use of the "cost plus" system, under which many million pounds' worth of work has been carried out on this side of the water during the war.

In the opinion of the writer, we should regard it as a war emergency only. Under the "cost plus" system, or, as it is known here, the "prime cost plus profit" system, it is impossible to avoid decreased effort. There is no inducement to be economical or industrious. The writer holds that fair competition is a good thing. By competition the general level of effort is raised. One has only to think of the field of sports to arrive at this conclusion. The system is likely to have a disastrous effect on labor, there is no scope for tact in the management of men, there is constant interference and inspection on behalf of the owner, and there is no incentive to seize favorable opportunities of buying materials.

At the same time the writer admits that it is hardly to be expected that contractors generally will take risks to the extent they have in the past. While we have the present unsettled conditions, and with charges increasing all the time, there should be appropriate clauses inserted in the contract allowing for variation in the contract price to meet the increased cost of materials and advances in wages. The writer cannot believe that the "cost plus" system will ever be extensively adopted either in Great Britain or America under normal industrial conditions.

Mr. French.

R. D. FRENCH,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer has been much interested in the discussion of this paper on contracts.

One of the prominent construction firms in Montreal has been utilizing the "cost plus percentage" contract with a rebate to the owner on the actual cost of the work. The following illustrations will make its mode of operations clear:

1. *Actual Cost Exceeds Estimated Cost:*

Estimated cost	$100 000
Estimated commission, 20% of estimated cost	20 000
Actual cost	110 000
Rebate, 10% of actual cost	11 000
Commission earned, $20 000 — $11 000	9 000
Total cost to owner, $110 000 — $11 000 + $9 000	108 000

* Montreal, Que., Canada.

Mr. French.

2. *Actual Cost Less Than Estimated Cost:*

Estimated cost	$100 000
Estimated commission, 20% of estimated cost	20 000
Actual cost	92 000
Rebate, 10% of actual cost	9 200
Commission earned, $20 000 — $9 200	10 800
Total cost to owner, $92 000 — $9 200 + $10 800	93 600

The writer is informed that this contract has given satisfaction in the few cases it has been used, and it appears to do away with one of the objections to the straight "cost plus percentage" form, in that the contractor has some incentive to keep the cost of the work down.

Mr. Ledoux.

J. W. LEDOUX,* M. AM. SOC. C. E. (by letter).—Mr. Clarke has presented exhaustively the merits of the "cost plus" system of letting contracts. Under ideal conditions, where the contractor and his force are actuated by fairness and honesty, the system is undoubtedly equitable to both the contractor and the owner, but there is enough evidence in the administration of recent contracts, especially in most of those carried out during and continuing after the war, to prove that the system is capable of the greatest injustice to the owner, and of profiteering. Even where the contractor himself may desire to be fair to his principal, the very fact that it is to his advantage to have the work extend over a long period and cost more than the estimate permeates the entire organization from the superintendents to the lowest paid laborers. It takes away all the responsibility and the impetus for despatch and economical construction.

The writer ventures to say that many of the most important projects carried out on this system might have been done for one-third or one-half the cost under one that would have been to the interest of the contractor to finish the work in the shortest time and at the lowest cost, which is the ideal system. No one has been able to devise a form of contract that will realize this ideal. Therefore, any system that is recommended must be defective in some part.

The usual contracting systems are: The "lump sum", the "unit price", the "cost plus a percentage", and the "cost plus a fixed sum". Some projects lend themselves to the lump-sum bid; such, for instance, as the construction of a pumping engine, a water tower or a lighthouse, where there may be no subsequent necessity for deviating from the original plans. The lump-sum bid is not well suited to the construction of a dam or reservoir or any structure where the quantities are likely to differ from those shown in the original plans, in which cases the unit price system is applicable. Both these systems, however, give the owner the advantage and impose on the contractor

* Philadelphia, Pa.

serious risks. If the work is let to the lowest bidder he must often compete against unduly low bids. If he gets the work he takes all risk of unfavorable conditions, while the owner takes only the risk of increased quantities. In the percentage and "cost plus" methods there is a premium on inefficiency and profiteering, and the advantages lie wholly with the contractor, who takes no risk whatever. Mr. Ledoux.

Engineers have tried to overcome these difficulties without imposing injustice on the contractor. Probably one of the best methods is to invite bids on a unit-price basis, with the proviso that the most acceptable bidder is to be willing to take the work as an alternate on a fixed profit basis. Then the owner, through his engineer, may call in the acceptable bidder and decide on the amount of profit he is willing to pay, regardless of the cost; the work is done on a cost basis plus the fixed profit, and the contractor is permitted to participate in the saving in cost to the extent of from 25 to 50 per cent. This bonus will be sufficient to induce the contractor to expedite the work as much as possible and it will be to the interest of every one connected with the construction to complete the work at the lowest price and in the shortest time. This method may appear to be difficult of application, but the difficulties are more apparent than real. A complete understanding must be had with the contractor as to whether, and how, overhead charges and plant rental are to be included in cost.

Another method of overcoming the difficulty is to select a contractor who has established a reputation for economical construction on the "cost plus" basis, but this method is manifestly unfair to many deserving contractors whose reputations are not so well known.

In any case, the interests of the owner in regard to quality of work can be safeguarded only by honest and capable engineering supervision.

Mr. Clarke.

ERNEST WILDER CLARKE,* M. AM. SOC. C. E. (by letter).—As stated at the time of presenting the paper the writer was principally anxious to induce discussion on a subject which seemed to him to be worth it, especially at this time, and he hoped that such discussion might bring out statements that would indicate the wisdom or otherwise of a more general use of the "cost plus" contract. Unfortunately, with one exception, there has been little but expressions of personal opinion which, while interesting and instructive, are not proof either for or against this form of contract, and he does not consider it worth while to continue to great length further discussion based on such grounds.

Conditions during the war were so abnormal that excessive costs of work should not be charged to any form of contract—organizations for supervision were improvised over night and naturally did not function smoothly at once. The contractors' organizations were also greatly expanded to care for the vast increase in their work, and

* Baltimore, Md.

Mr. Clarke.

inevitably the two organizations failed, in many cases, to evolve the cheapest methods of doing the work. As the war went on, this handicap was largely overcome, and there were many cases where the supervising engineers and their forces and the contractors and their forces worked together most successfully to devise means to reduce the cost of the work. The high cost of labor and material largely masked such efforts, however, and very little credit will ever be given for real economies effected in spite of adverse conditions. In other words, war-time costs were so far above those of peace times that the fact that they might have been still higher except for the efforts made by the two parties is not appreciated. The contractors are blamed for things of which they really were the victims and over which they had no control. Mr. Frankland states that "this form of contract would 'smell to high heaven'" on some "cost plus" contracts. If this statement is true, it implies connivance on the part of the supervising forces or at least such disregard of their obvious duty that it amounts to connivance, and any one having proof of such conditions should bring the facts to the attention of officers who could punish the guilty persons.

This is not the place to enter into a discussion of the causes of the high costs of war construction, but as the writer had intimate knowledge of conditions on a dozen or more large and small "cost plus" jobs, with large and small contractors at work during 1917 and 1918, he feels himself competent to assert that after the organizations reached a good working condition both parties to the contracts did everything possible to make the work as inexpensive as conditions of the market permitted, and that intentional loading of the pay-roll, loafing on the job, or unnecessary purchases, were neither permitted nor attempted, the contractors' foremen being generally as zealous in crowding their men as on lump-sum and with-price jobs.

The writer does not agree that the use of "cost plus" contracts is an admission of inability to write clear and definite specifications. He had the honor to assist in writing some of the specifications of the New York Board of Water Supply, and is familiar with the extreme care used in order to make those specifications clear and fair to both the city and the contractor; almost every word was scrutinized for an ambiguous meaning, and where any doubt existed as to the exact meaning explanatory phrases were introduced or other more definite word or words substituted. Later, he was in charge of construction under these specifications and learned how many different interpretations contractors' superintendents and engineers could propose for words which he supposed had only one meaning. Most of these disputes were settled amicably, but they were all potential suits, and the mere fact that they were possible is indicative of the extreme difficulty

of writing specifications that will prevent misunderstandings. This is not intended as an argument for the elimination of specifications, but merely as indicating that disputes are not always due to carelessly drawn specifications. Mr. Clarke

The writer still believes that an engineer is, and properly is, "biased" in favor of his employer, the owner; the engineer is hired for the specific purpose of protecting the owner against the contractor's errors, whether or not such errors are intentional, and it is his duty to require the contractor to prove the justice of any claim involving the reading of the contract or specifications; the fact that in many cases the contractor is able to satisfy the engineer that his claims are just and that in such cases the engineer has fought to secure the acknowledgment by the owner of the claims merely accentuates the fact of the prior bias of the engineer.

The one discussion which gave the result of experience with lump-sum and "cost plus" contracts is the best evidence that the latter form, when handled by intelligent and honest contractors, is favorable for both sides to the contract. Presumably, the owners of the jobs covered by Mr. Perry's discussion had engineers or architects representing them and, doubtless, some of these men made suggestions or even ordered methods that resulted in decreased costs.

Engineers are apt to assume a rather sanctimonious attitude toward contractors, to hold that engineers are honest, but that contractors require strict watching to prevent very serious wrong-doing. As a matter of fact, intelligent self-interest forces a reputable contractor to do work which will bear inspection and which will serve as an advertisement of good work and not bad. As men, they are, nowadays, of the same class and education as engineers, and have as high a sense of honor. The writer has had the pleasure of knowing many contractors whose simple word is a guarantee of faithful work and, with such men, the engineer's part on the job is largely that of staking out the work, interpreting the plans and specifications when any ambiguity is discovered, and, in general, making inspections to see that mistakes are not made.

All engineers are expected, and practically all do, work against their own financial interests. Almost invariably they are supposed to push the job in every way they can, to work overtime without any extra pay in order to avoid delay in the work; to order their work so that the construction is not held up—in short to do everything possible to get themselves out of a job and have a chance to hunt for another on their own time.

The writer has yet to find a gang which, as a whole, failed to live up to the expectation that it would in this way work against its immediate and most apparent interest, and he believes that another

Mr. Clarke.

gang which is different only that it is employed by a contractor would perform in the same way, if its chief made it plain that he expected such an attitude, and many contractors have and would make it very plain that that was their expectation. A reputation for such an attitude would be the best guarantee the contractor and his forces could have that, good times or bad, owners would offer them work and that, unlike the engineer, neither the contractor nor his men would have to hunt for work on their own time.

As for the engineer, the "cost plus" offers him a chance to show both executive and constructive ability—to make it evident to the owner that he has saved money for him by methods whereby costs have been reduced, by taking advantage of favorable developments of the site, or by overcoming unfavorable developments at minimum expense.

As chief inspectors, engineers now get credit at the most for negative results—they prevent bad work. It is utterly impossible to evaluate such service in dollars, and little effort is made to do so; their services as designers are largely forgotten after the plans are accepted and work begun and the owner regards them as he regards insurance, as an overhead expense to be cut to the minimum possible. The contractor often thinks that engineers are more or less impractical theorists with whom he has to put up, but who can cause him much loss by insisting on contract or specification interpretations which, to his mind, are unreasonable.

As a matter of fact, on jobs of any size, the engineer is generally the man best informed as to local conditions, methods of work likely to produce good results at minimum expense, and plant required. He has spent weeks, months, possibly years, studying the plans and the site and has a fund of knowledge that is only partly reflected in the plans and specifications. After a lump-sum or item contract is let, the contractor, if he is wise, consults with the engineer and revises his own plans and methods as far as he is convinced of the soundness of the engineer's ideas. Any saving made from such revision generally goes into the contractor's pocket. The owner may gain indirectly by increased speed, but the knowledge of his employee principally benefits the contractor. On a "cost plus" contract, where the owner and the contractor are working in harmony, the engineer becomes a vital part of the machinery. His knowledge and his experience are direct assets to the owner, the contractor, and himself; he ceases to be a spectator of the construction of the work he designs, and is an active participant in methods, plant layout, and responsibility. The writer believes that in endeavoring to relieve owners of responsibility for the contractor's acts, engineers have also relieved themselves so entirely that

they have become mere layers out of work to a large degree, and, as such, receive the wages of subordinates instead of the rewards of creators. Mr. Clarke

It goes without saying that no one form of contract would apply to all work, and this appeared so self-evident that the point was not mentioned in the paper. The generic term "cost plus" was also used because it was recognized that many possible forms of this type existed and many more could be written, although the paper was not an advocate of any particular form. A form such as Mr. Waddell suggests might be applicable to some contracts, other forms to other contracts.

Many schemes for "letting" whereby competition would be secured and the elimination of new firms avoided could be evolved. The engineer's estimate of probable cost would be expected to show the owner in advance the approximate amount of money involved and with the engineer as the owner's representative in full control of expenditures, it would be his duty to keep the expenditures within that limit or explain the reason for failure to do so. It would also be to the engineer's credit if savings were made, and a reputation for ability to keep ultimate costs below the estimate would enable him to demand adequate payment for such service.

The statement has been made repeatedly that under a "cost plus" contract the contractor has no incentive to save money for the owner. This statement does not do credit to the contractor's business sense.

Firms looking for work under such contracts must be able to refer a prospective client to the owners of jobs they have done and be able to show by the cost records of such jobs that economy was effected, otherwise their first job would be their last. As a matter of fact, a record of low costs becomes the most valuable asset of such a contractor and of far more importance than the money that might be made on one or two jobs by running the cost into high figures. The owner is supposed to exercise care in the selection of a contractor and to have the work properly supervised. If he does neither of these things, he may pay a very high price for his structure, but such an owner would be just as likely to be cheated on a lump-sum or item contract.

The use of the "cost plus" form on public work is evidently a much more dangerous thing than on private work, but only on account of the political complication. If experience proves that the form is economical for private owners, some scheme could be devised by which the public also could be benefited.

Some contractors may "enjoy the gamble", but probably they enjoy it the most when they are sure they will not lose; where they have added enough to their item charges or their lump sum to provide for anything short of a general cataclysm and have been awarded the job not on account of their optimism but because of the greater pessimism of the other bidders.

Mr. Clarke.

In the long run, nobody is benefited by a business failure. Some owner may get a job done below cost, but workmen and supply men suffer, and wherever possible the loss is passed on to some other job. Any scheme that tends to prevent failures is a step in the right direction, provided new dangers are not thereby introduced, and "cost plus" contracts can be written and applied so that these new dangers are avoided to a great extent.

If the paper and discussion has the effect of bringing the matter more generally to the attention of engineers, the writer's object is attained. He believes that the "cost plus" contract in one form or another is suitable for use on many jobs and that its use would result in good for owner, contractor, and engineer.

Paper No. 1442

COMPREHENSIVE PLOTTING OF WATER TURBINE CHARACTERISTICS

By Karl R. Kennison, Assoc. M. Am. Soc. C. E.

Synopsis.

This paper presents a chart for the comprehensive plotting of water turbine characteristics. The use of this chart would enable the manufacturer of a water-wheel to show simply and clearly the performance of his turbine under any and all conditions. It would enable the purchaser intelligently to weigh the merits of different turbines and their compliance with specified requirements.

The arrangement of the paper is as follows:

1. The Need of Comprehensive Plotting.
2. Specific Characteristics of Water Turbines.
3. Description of the Chart.
4. Typical Water Turbines of American Manufacturers.
5. Method of Using the Chart.

1. The Need of Comprehensive Plotting.

The test performance of a water turbine is most commonly represented by a series of curves, one for each gate-opening used in the test. Two, or sometimes three, sets of such curves are usually presented. For all these curves the horizontal scale is laid off in terms of the speed under a given head. For one set the vertical scale is efficiency, for the other, it is power output, and sometimes a third set is added, showing the discharge.

Such curves do not give a sufficiently clear indication of the results that would be obtained at any other gate-opening not included in the tests. An engineer, if he has made a study of the performance of water turbines—but not unless he has made such a study—can interpret these curves and fit them to any desired conditions of head, speed, discharge, etc. Most engineers, however, are busy men, and after learning that the specific speed of a water turbine is that speed at which it would run under a 1-ft. head, if they could imagine it reduced in size until it developed only 1 h.p., they give it up as a bad job.

The following diagrammatic method of showing the performance of a water turbine has proven so simple and convenient to the writer, that he presents it for the consideration of hydraulic engineers and turbine manufacturers.

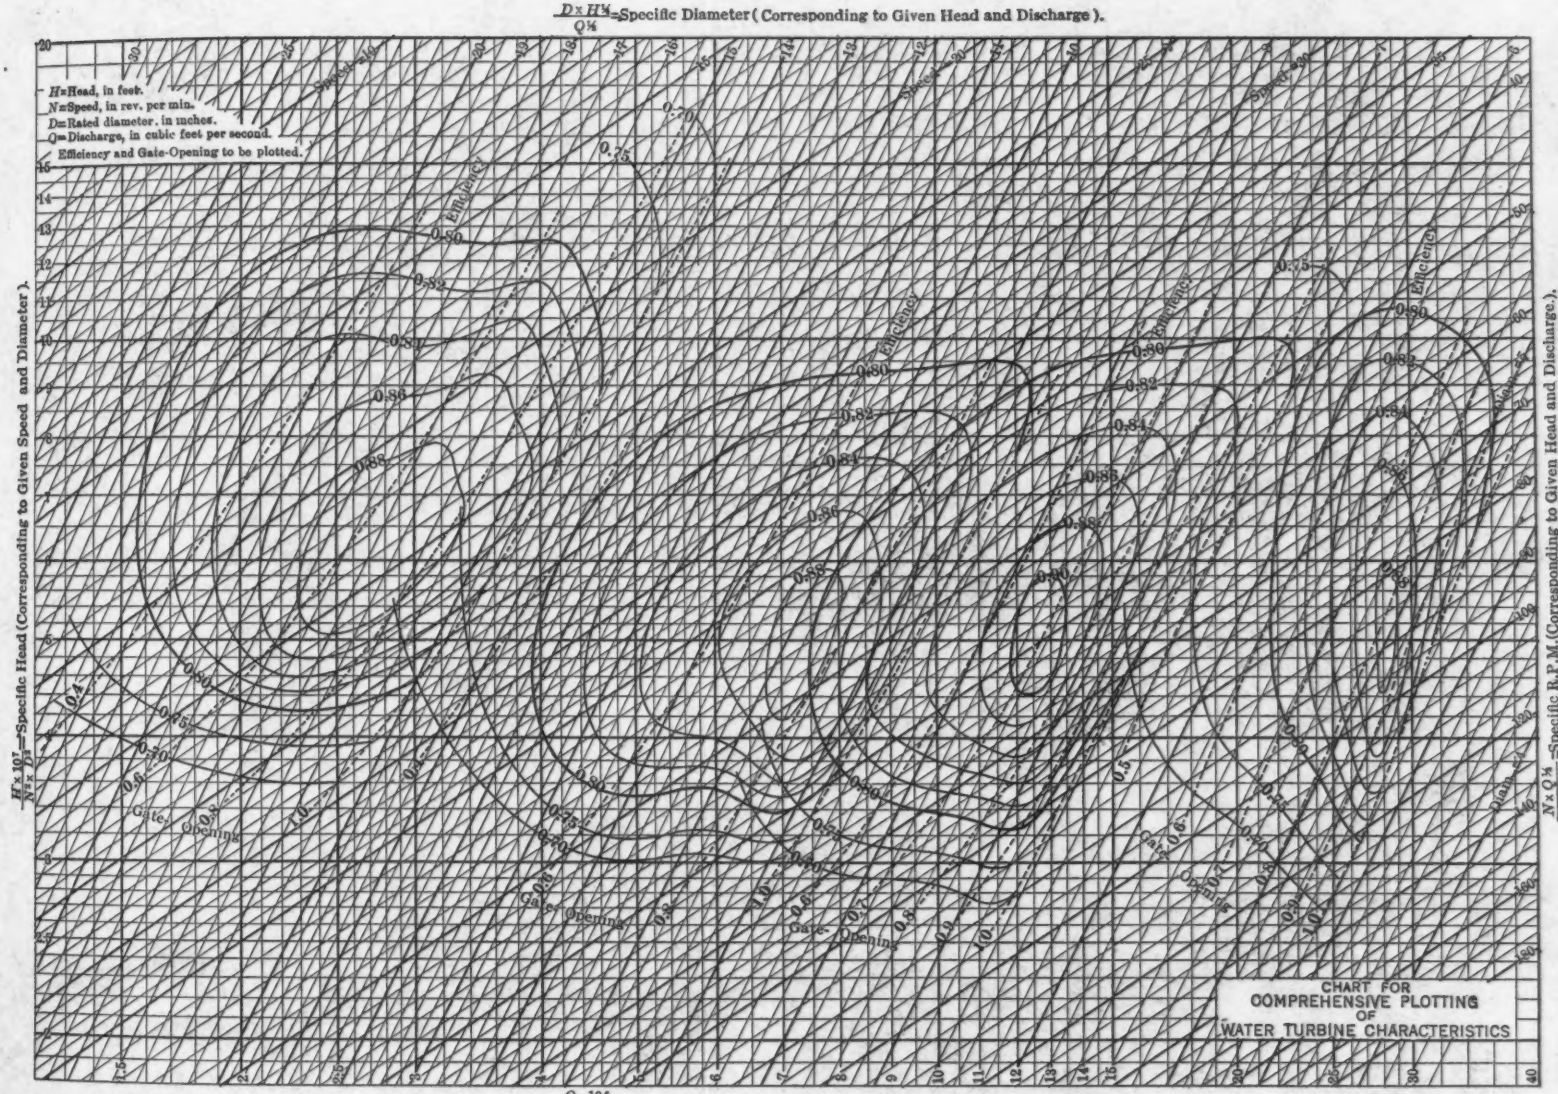
2. Specific Characteristics of Water Turbines.

We are concerned with seven variable quantities. It is, of course, the large number of variables which so complicates the problem. For convenience, let us refer to them by the following letters:

D = rated diameter, in inches.
H = head, in feet.
N = speed, in revolutions per minute.
P = power output, in horse-power.
Q = discharge, in cubic feet per second.
Gate-opening.
Efficiency.

For various reasons large units may show a slightly increased efficiency over small models under all conditions of operation, but it is aside from the purpose of this paper to discuss the extent of such an increase, and no further account will be taken of it. No attempt will be made to discuss the design of turbines, but certain characteristics will be stated as concisely as possible.

It is characteristic of water turbines that when any given design or type is varied in diameter, all the dimensions, of course, being kept in proportion, the efficiency will remain the same, at the same gate-opening, if N is varied directly as $\sqrt{H}$ and inversely as D; and the resulting P will vary directly as $H^{\frac{3}{2}}$ and as D^2, and Q will vary directly as $\sqrt{H}$ and as D^2.



$\frac{D \times H^{\frac{1}{4}}}{Q^{\frac{1}{2}}}$ = Specific Diameter (Corresponding to Given Head and Discharge).
H = Head, in feet.
N = Speed, in rev. per min.
D = Rated diameter, in inches.
Q = Discharge, in cubic feet per second.
Efficiency and Gate-Opening to be plotted.
Efficiency
Gate Opening
$\frac{H \times 10^7}{N \times D^2}$ = Specific Head (Corresponding to Given Speed and Diameter).
$\frac{N \times Q^{\frac{1}{2}}}{H^{\frac{3}{4}} \times 10^4}$ = Specific R.P.M. (Corresponding to Given Head and Discharge).
(Numerically Equal to "Specific Speed" at 85% Eff.).
$\frac{Q \times 10^6}{N \times D^3}$ = Specific Discharge (Corresponding to Given Speed and Diameter).
CHART FOR
COMPREHENSIVE PLOTTING
OF
WATER TURBINE CHARACTERISTICS

Hence, the following are twelve simultaneous constants:

Efficiency,	Gate-Opening,	$\frac{N\,D}{\sqrt{H}}$,
$\frac{P}{D^2\,H^{\frac{3}{2}}}$,	$\frac{Q}{D^2\sqrt{H}}$,	$\frac{P}{D^5\,N^3}$,
$\frac{Q}{N\,D^3}$,	$\frac{P\,D^4}{Q^3}$,	$\frac{N\sqrt{Q}}{H^{\frac{3}{4}}}$,
$\frac{P}{Q\,H}$,	$\frac{P^3}{N^4\,Q^5}$,	$\frac{N\sqrt{P}}{H^{\frac{5}{4}}}$,

Of these constants, the last is the one commonly known as the "specific speed." It is that constant which expresses the relation between speed, head, and power.

Of the seven variables referred to, only six are independent variables, since power output and discharge are inter-related through the efficiency. Simplification demands that either P or Q be eliminated from consideration. The writer is aware that he is departing from present practice in eliminating power output and retaining discharge capacity.

Performance curves are usually drawn to show the horse-power output, and with good reason, as the turbine user is looking for results, and the power output is certainly the result in view. However, the problem before the engineer usually involves a given head and a given discharge—to find the turbine which will give the greatest efficiency. The head and discharge are the fundamental quantities with which we have to deal.

For example, the so-called specific speed of a turbine, already referred to, is the criterion by which we judge whether it is of the right type to do its best at suitable speed under relatively low head and high discharge, or *vice versa*. Two turbines may be of the same type in this respect, and yet one may be much more efficient. Hence, the writer claims that the specific speed should properly show the relation between speed, head, and discharge, instead of between speed, head, and power.

Therefore, the type characteristics of a water turbine may be obtained from the previous list of simultaneous constants by omitting those involving the power output. The form in which they are ex-

pressed subsequently has been chosen for convenience of mathematical expression. On account of taking advantage of a fortunate mathematical coincidence, what the writer proposes to call "specific r. p. m.", or the relation between speed, head, and discharge, is numerically equal to the "specific speed" currently expressed as the relation between speed, head, and power, at the efficiency attained by wheels of good design, namely, 88 per cent. Hence, the two terms are practically interchangeable in any general reference to approximate values.

The characteristics are as follows:

$$\text{Specific head} = \frac{H \times 10^7}{N^2 D^2}$$

$$\text{Specific discharge} = \frac{Q \times 10^6}{N D^3}$$

$$\text{Specific diameter} = \frac{D H^{\frac{1}{4}}}{Q^{\frac{1}{2}}}$$

$$\text{Specific r. p. m.} = \frac{N Q^{\frac{1}{2}}}{H^{\frac{3}{4}} \times 10^{\frac{1}{2}}}$$

3. Description of the Chart.

The chart is simply a means of plotting efficiency and gate-opening in terms of the four fundamental type characteristics listed previously.

The plotting of test data of any turbine on this chart tells the complete story of the performance of this type or design of turbine, regardless of actual head, discharge, diameter, or speed of the turbine in question; and the plotted result can then be used to show the expected performance under any other desired head, discharge, diameter, or speed.

As the co-ordinate scales for plotting are fixed and can easily cover the entire range of turbine design, the difference between one type of turbine and another is shown at once by the relative location on the chart. For example, nearness to the lower right-hand portion of the chart means high speed and small diameter. Moreover, of several types which plot equally near the lower right-hand portion, the lowest is relatively the fastest and largest and the farthest to the right relatively the slowest and smallest.

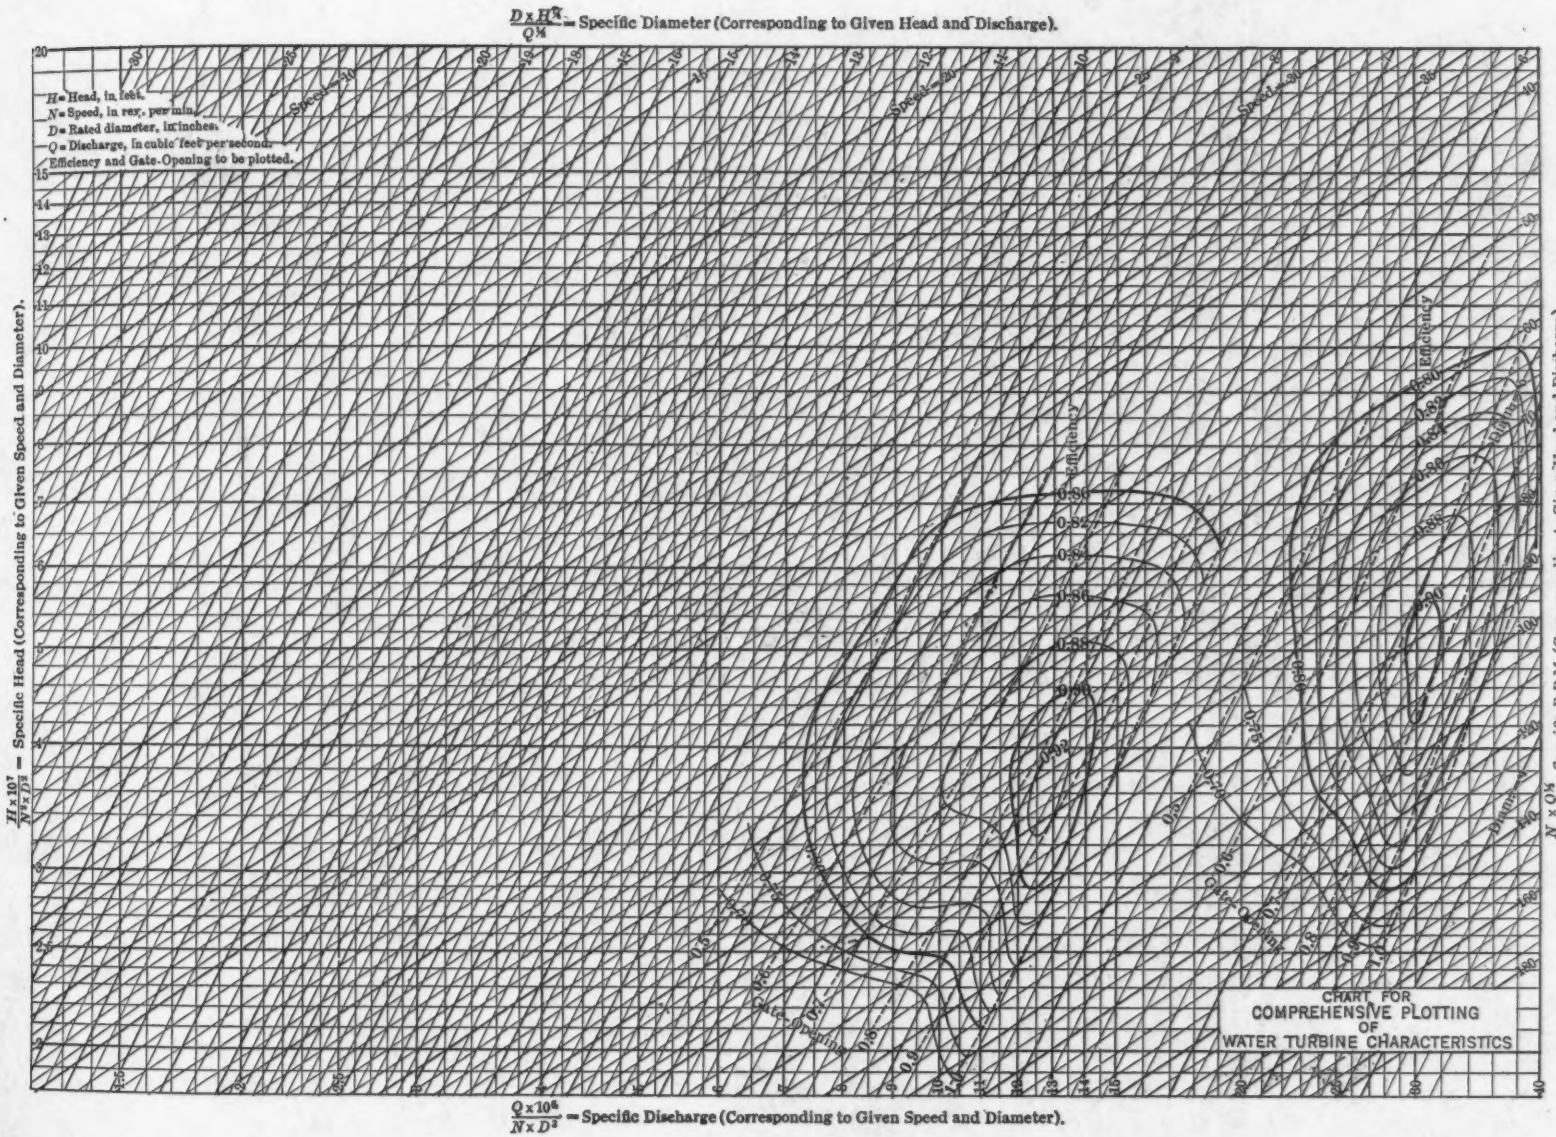
KENNISON ON
PLOTTING OF
WATER TURBINE CHARACTERISTICS.



The vertical and horizontal scales represent the two most important variables with which we have to deal, namely, head and discharge, respectively, so that when the characteristic curves are plotted for any type of turbine, the available range of head and discharge stands out very clearly.

On account of the logarithmic scale of the co-ordinates, the range of operation of any two types may be compared regardless of their location on the chart. For example, the vertical distance enclosed by the 80% efficiency line is the measure of the percentage variation in head in which this efficiency is equalled or exceeded, and, similarly, the horizontal distance is a measure of the percentage variation in discharge. In this respect, a low-speed turbine at the left of the diagram is directly comparable with a high-speed turbine at its right.

4. Typical Water Turbines of American Manufacturers.

Only inward and downward flow turbines are represented. Plate XII shows the characteristic curves of four turbines made by one American manufacturer, covering a wide range of conditions. The specific speeds, at most efficient operation, are, as shown by the chart, approximately 25, 47, 61, and 90. A glance shows that high specific speed is evidently obtained at a sacrifice in efficient range of discharge capacity.

Plate XIII shows the characteristic curves of two turbines made by another American manufacturer, the specific speeds being approximately 77 and 96. The first turbine is highly efficient. It plots low down on the chart, indicating a relatively large diameter. It should be borne in mind that the rated diameter is a more or less arbitrary dimension and that it depends on the amount the runner vanes are cut away. However, the point of measurement of diameter being once determined, the chart gives as exact relations in the case of the diameter as of any other variable. The second turbine is remarkable for its combination of high specific speed and comparatively large range of efficient operation.

A great deal of information as to the performance of American water turbines, of the inward and downward flow type, is condensed in Plates XII and XIII.

5. Method of Using the Chart.

Plate XIV shows at the right a third American manufacturer's turbine with a specific speed of about 91. The method of using the chart is described very briefly, as follows:

Suppose this type of turbine is proposed for the development of an available normal discharge of 240 cu. ft. per sec. per wheel, under a normal head of 30 ft., subject to variation from, say, 24 to 32 ft., often enough to require high efficiency at these heads.

Knowing that $H = 30$ ft. and $Q = 240$ cu. ft. per sec., the scale of "specific r. p. m." can be easily converted into one of speed expressed in revolutions per minute. This scale has been added to the chart at N. Only those speeds are marked, which will give the required 60 cycles per sec. Similarly, the scale of specific diameters can be easily converted into one of diameter expressed in inches. This scale has been added to the chart at D. Only those diameters are marked, which the manufacturer can furnish from stock patterns.

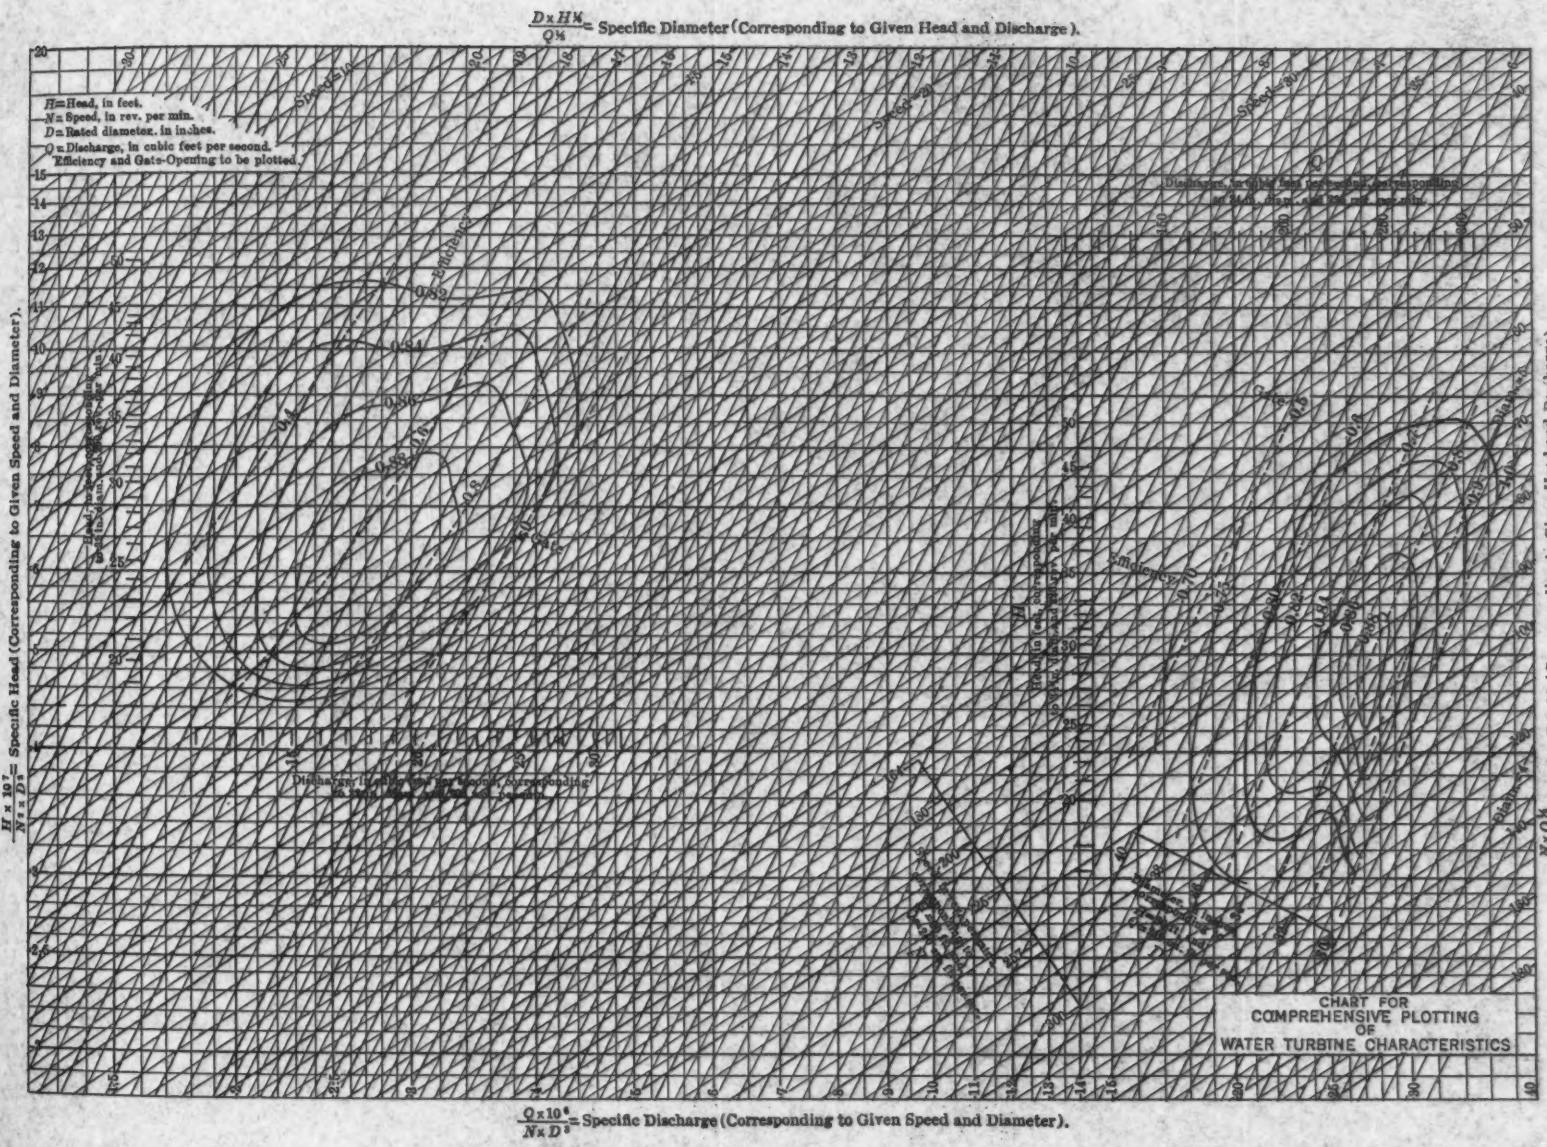
The speed and diameter may then be chosen so that the turbine will do its best under the given conditions of operation. The chart shows that, at 225 rev. per min., a 34-in. wheel will operate at near its peak efficiency and, at the same time, allow efficient operation at a considerable reduction in head and increase in discharge. Hence, this speed and diameter are determined on.

Then, knowing $N = 225$ rev. per min. and $D = 34$ in., the scale of specific heads can be easily converted into one of head expressed in feet, and the scale of specific discharges into one of discharge expressed in cubic feet per second. These scales have been added to the chart at H and Q and enable the performance of the selected wheel to be predicted under all conditions of operation. For example, the chart shows:

Under a 24-ft. head: a gate-opening of about 0.64 will pass a discharge of about 180 cu. ft. per sec., without the efficiency going below 80%; a 0.90 gate will pass about 240 cu. ft. per sec., at an efficiency of 87%; and full gate will pass about 260 cu. ft. per sec., at an efficiency of 84 per cent.

Under a 32-ft. head: a gate-opening of about 0.60 will pass about 190 cu. ft. per sec., without the efficiency going below 80%; an 0.80 gate will pass about 250 cu. ft. per sec., at an efficiency of 88%; and full gate will pass about 290 cu. ft. per sec., at an efficiency of 83 per cent.

PLATE XIV.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXXIII, No. 1442.
KENNISON ON
PLOTTING OF
WATER TURBINE CHARACTERISTICS.



The peak efficiency of approximately 88.5% will be attained at about 0.82 gate, with a discharge of 240 cu. ft. per sec., under a 28-ft. head, and nearly if not quite as high efficiency under the normal head and discharge of 30 ft. and 240 cu. ft. per sec., at 0.79 gate.

To supplement the added scales of head and discharge, a set of curves showing actual horse-power delivered under all conditions could be added very easily, running in the upper left to lower right direction.

To illustrate the fact that distance, regardless of location, on the chart is a measure of range of operation, scales of discharge, in cubic feet per second, and head, in feet, have been added in the left-hand portion of Plate XIV to show the performance of a 32-in. wheel of low specific speed, operating at 200 rev. per min. Note that the spacing of these discharge and head scales is identical with that of the discharge and head scales for the high specific speed wheel at the right.

Paper No. 1443

THE SILT PROBLEM OF THE ZUNI RESERVOIR

By H. F. Robinson, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Elwood Mead, Clarence S. Jarvis, George M. Post, and H. F. Robinson.

Synopsis.

This paper discusses the silting up of reservoirs in the arid part of the United States, with special reference to the Zuni Reservoir in New Mexico, which shows a loss of capacity of 60.7% in 12½ years.

In all reservoirs built in the western part of America, and especially in those built in a stream bed by damming the channel, the silt problem is one that must be faced sooner or later; and unless some means can be found for removing the silt deposits, the accumulation will impair, materially, the storage capacity of the reservoir, and, at some date, controlled by local conditions, the entire basin will be filled to the brim.

This is particularly true of the ephemeral, flashy streams, dry a considerable portion of the time and subject to freshets and floods at intervals. At such times the floods of water coming down the dry beds will erode the bottoms and banks to a great extent, much more so than if the stream bed was continually wet, and the accumulation in the reservoir will be much greater when the reservoir is in the stream channel, as the entire débris of the erosion, whether carried in suspension by the water or rolled along the bottom, will be deposited in the reservoir.

The Zuni Reservoir is in the Zuni Indian Reservation in Western New Mexico, about 45 miles south of Gallup. It is formed by the

construction of a dam across the Zuni River, a tributary of the Little Colorado.

The dam is a combination rock and hydraulic fill, and was built by John B. Harper, M. Am. Soc. C. E., Superintendent of Irrigation in the U. S. Indian Irrigation Service. The rock fill has a height of 80 ft., or from the bottom of the puddle trench to the top of the parapet, 110 ft., the length over all being 780 ft. There are 40 000 cu. yd. of rock in the fill, and 60 000 cu. yd. of the hydraulic fill. At the point where the dam is built, the stream has cut through a lava flow, and the two abutments are composed of the lava or basalt.

The reservoir was built between 1902 and 1907, the gap in the stream being closed in 1906, from which time water was impounded; but, until August, 1909, only a small portion of the reservoir capacity had been stored.

In September, 1909, the water in the reservoir reached the spillway lip, and, it is supposed, found vertical cracks in the basalt south abutment of the dam, allowing the water to reach a stratum of sand under the basalt, causing a subsidence of the mesa, which wrecked the spillway and damaged the end of the dam.*

As originally constructed, the spillway of the Zuni Reservoir was at Elevation 1 000, but when the new spillway was built, it was placed 9 ft. lower. It was planned that when more storage capacity was needed some form of stop was to be placed in the spillway, either a permanent weir, or gates of some kind, with the top edge at the old elevation, and proper foundations were placed under the floor of the spillway to allow for this.

The quantity of silt brought into this reservoir is very great, and in the 12½ years since the channel was closed, has amounted to about 4.86% per annum of the reservoir capacity to the elevation of the present spillway.

Soundings were made in the reservoir in June, 1910, January, 1912, January, 1914, and January, 1918, in order to ascertain the quantity of silt deposited. With the exception of the first period (from June, 1906, to June, 1910), when the run-off was not carefully measured, the run-off records have been kept with considerable accuracy, and

* An article describing this failure appeared in *Engineering News*, Vol. 62, pp. 597 to 600, and an article relative to the flood of that time, and an attempt to find the relation between the records of the run-off and rainfall appeared in *Water Supply Paper No. 269* of the U. S. Geological Survey, p. 206. This same article also appeared in *Engineering News*, Vol. 64, pp. 203 and 204.

as the last three sets of soundings were taken through the ice, and the measurement points located with a transit, it is thought that the results obtained are of considerable accuracy.

During the first period, which was 4 years, the quantity of silt deposited was 1 804 acre-ft., an average of 451 acre-ft. per year. During this period, the estimated flow was 56 140 acre-ft., which is thought to be slightly in excess of the actual flow; but, assuming it to be correct, the quantity of silt deposited was 3.2% of the run-off.

During the second period (1½ years), the silt deposit amounted to 1 340 acre-ft., or 894 acre-ft. per year. The run-off was 24 630 acre-ft., and the silt was 5.4% of this flow.

The third period (2 years) had a run-off of 14 360 acre-ft. The silt deposited was 1 056 acre-ft., or 528 acre-ft. per year, and the percentage of silt to the run-off was 7.3, the greatest in any period.

During the fourth period, the conditions of run-off were very different. The seasons were wet, and although the run-off was many times the quantity of the former periods, the silt deposited seems to have been considerably less than in former years. There is found to be a total deposit for the 4 years of 1 307 acre-ft., or 329 acre-ft. per year, but as the run-off for the period was 226 195 acre-ft., the silt percentage was only 0.58.

For the total period of 12½ years, the run-off has been 326 648 acre-ft., the silt deposit, 5 507 acre-ft., and the average silt content, or deposit of the water, 1.88 per cent.

In addition to this silt deposit, which only represented the quantity left in the reservoir, a considerable quantity has been carried out of the reservoir through the gate-valves, and, during the last period, it is probable that a large quantity carried in suspension passed over the waste-way. Considerable water has been wasted through the valves back into the river, such waste having been necessary, especially of later years, in order to keep the valves clear, and some muddy water was drawn off for use on the fields.

It was estimated by the Engineer in Charge that each year during the third period, at least 50 acre-ft. of silt went to the fields and at least three times this quantity went back to the river, through the valves, with the waste water. How much has been carried out during the past four years, or what proportion of silt was in the water passing

over the waste-way, there are no records to show, but the quantity is not inconsiderable. (See Table 1.)

TABLE 1.—SILT DEPOSIT IN THE ZUNI RESERVOIR FROM ORIGINAL CLOSING OF CHANNEL IN 1906, TO JANUARY 1ST, 1919.

All Capacities and Silt Deposits in Acre-Feet.

	Original, 1906.	June, 1910.	Jan., 1912.	Jan., 1914.	Jan., 1918.	Jan., 1919.	Total period.
Total silt deposit	0	1 804	3 144	4 200	5 507	6 186	6 186
Length of period, in years	.....	4	1½	2	4	1	12½

Silt per year, average	.....	451	894	528	327	678	494
Total run-off	.....	56 140	24 630	14 360	226 195	5 323	326 648
Percentage of silt in run-off	.....	3.2	5.4	7.3	0.58	12.5	1.88
AT CONTOUR 990:							
Capacity	10 230	8 409	7 069	6 013	4 706	4 028	4 028
Percentage remaining of original capacity	.....	82.3	69.2	58.8	46.0	39.3	39.3
Lost capacity per year in percentage of original	.....	4.4	8.8	5.2	3.2	6.7	4.86
AT CONTOUR 1 000:							
Capacity	15 811	13 969	12 632	11 562	10 218	9 540	9 540
Percentage remaining of original capacity	.....	88.4	80.0	73.1	64.6	60.3	60.3
Lost capacity per year in percentage of original	.....	2.9	5.6	3.48	2.1	4.3	3.17

Life of reservoir, Contour 990 = 21 years. Spillway at Contour 991. Capacity between Contours 990 and 991 = 507 acre-ft.
Life of reservoir, Contour 1 000 = 32.4 years.

Considering the reservoir at its present construction (see Table 2 and Fig. 1), the original capacity at Contour 990 (1 ft. below the present spillway lip), was 10 213 acre-ft. At the end of the first four years, it was 8 409 acre-ft., a loss of 4.4% each year, leaving the capacity 82.3% of the original. At the end of the next year and a half the capacity was 7 069 acre-ft., a loss of 8.8% per annum, with

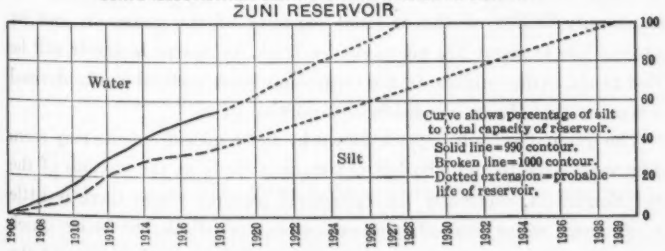

FIG. 1.

69.2% of the capacity of the reservoir remaining. At the end of the third period (two years later), the capacity was 6 013 acre-ft., a loss of 5.2% per annum. At the end of the next period, the capacity was 4 706 acre-ft., or only 46% of what it had been 11½ years before; and, at the end of the last period, the capacity was only 4 028 acre-ft., 39.3% of its original capacity. The average capacity lost each year was 4.86%, and the average lost per year for the entire 12½ years was 4.86 per cent.

This means that the life of the reservoir to Contour 990 will be a little more than 21 years, of which 12½ years have passed. At this rate, the reservoir will be silted to within 1 ft. of the spillway level by June, 1926, and within a couple of years from the time of this writing (1919), the storage capacity will have been so impaired that it will not store enough water to carry the project over a normal year, and certainly not enough from a wet year to tide the project over a dry one.

TABLE 2.—CAPACITIES, IN ACRE-FEET, OF THE ZUNI RESERVOIR AT VARIOUS TIMES, SHOWING ITS REDUCTION BY SILT DEPOSITS.

991	.....	.....	.....	.....	5 213	.....
995	12 887	11 032	9 721	8 664	7 336	6 660
1 000	15 811	13 969	12 632	11 562	10 218	9 540

Similar data have been worked out with the spillway restored to the 1 000-ft. contour. (See Table 2.) At the present time, there remains only 60.3% of the original capacity of the reservoir, and its extreme life is about 32½ years, or, by 1939, the entire reservoir will be filled to the brim—unless, in the meantime, some method can be devised to remove the silt, or a considerable portion of it.

The quantity of silt deposit shown by these measurements may seem to be very large to one who has not made a study of the streams of the arid Southwest, especially the ephemeral streams where there is little or no clear water run-off, the entire annual discharge being quick floods after the summer rains or in the spring when the snows of the

higher elevations melt. Lake McMillan, in New Mexico, is reported to have silted up 60% in 15 years.* Taking the Zuni Reservoir at the 990-ft. contour, the percentage of filling would be about 70 in 15 years, and using the capacity of the reservoir at the 1 000-ft. contour, about 48 in the same time. In the reports concerning the Austin Dam, it is stated that in the 4 years, from 1893 to 1897, the reservoir was silted up 38% of the original capacity, and during the period of 7 years, from 1893 to 1900, it had silted up 48 per cent.

Mr. W. W. Follett† gives 1.66 as the mean percentage of silt carried by the Rio Grande, at San Marcial, N. Mex., from 1897 to 1912, inclusive. For the same period, the maximum was 4.14% in 1911 and the minimum 0.78% in 1905. He mentions the maximum for one day—October 7th, 1911—as 14.87% and the monthly mean of 7.9% for the month of October, 1911. It is probable that the maximum mentioned by Mr. Follett, namely, 14.87%, would represent about the maximum quantity ordinarily carried in suspension. There are exceptions, as will be shown later.

Some experiments made by Rollin Ritter, Assoc. M. Am. Soc. C. E., Engineer in Charge of the Zuni Reservoir, leads him to the following conclusions regarding the silt-ladened waters of the Zuni River, and some general conclusions regarding the quantity of silt that may be transported in some of these Southwestern streams. A report made by him in 1914, to the writer, contains the following statements:

"The silt-ladened waters being heavier than the clear, ofttimes appeared at the tunnel outlet when the reservoir surface was clear and a small or moderate flood was entering the reservoir. During one period, when the water wasted appeared very heavily charged with silt, a sample was taken at the tunnel outlet. This bottle test showed percentages of silt by volume at various times about as follows:

Time after collecting sample.	Apparent % of silt.
1 day	55
7 days	35
1 month	25
3 months	17½
4 months	16

"At the latter time, the silt in the bottle was compact and even showed lamination marks and probably no more shrinkage would have

* Third Annual Report of the U. S. Reclamation Service.
† *Engineering News*, January 1st, 1914 (Vol. 71, p. 18).

occurred. In the earlier periods when a sliver was plunged through the mouth of the bottle into the silt, the line of demarcation between the surface of the silt and supernatent clear water was not sensible to the touch. Unfortunately, the bottle containing the sample froze and burst, and the observations for a longer period could not be made.

"The above may illustrate why so many engineers regard the bottle test as worthless. It may also explain why some enormous percentages have been reported at times from various sources, *i. e.*, the silt as first observed will eventually shrink to one-third or even one-fourth the volume observed in the freshly gathered sample.

"No tests are available to solve the question of how much was carried by the water in suspension, and how much rolled down the stream bed. The latter is, however, a large proportion of the former."

Some measurements made by the writer on Bonito Creek near Fort Defiance, Arizona, gave something over 13% of sediment after the sample had stood 30 days. The most remarkable instance of large quantities of sediment carried by water was observed in the Moencopi Wash on the Painted Desert of Arizona. During a flood on this stream, a sample was dipped up from about the center of the thread of the stream and allowed to settle for two days, and remarkable as it may seem, at the end of that period, there was 15% of turbid water and 85% of sediment, showing that the flow of the stream was practically liquid mud. The sample was upset before it had time to settle further, but it is probable that a settlement of 30 days would have shown not less than 50% of solid matter.

Unfortunately, the Zuni Reservoir is situated in the bed of the stream, and all silt whether carried in suspension or rolled along the bottom of the stream bed is caught in the reservoir, except the comparatively small quantity that passes out through the valves, and the lighter portion of the sediment which is held in suspension and passes over the spillway at times when the water is flowing into the full reservoir. We have here a fairly large basin and a moderately high dam, and the entire closing up of the channel. "The greater the height of the dam or size of reservoir, the greater will be the rate of filling."* This is the opinion of the late H. F. Labelle, M. Am. Soc. C. E., after an examination of the silt question in many reservoirs and behind many dams both in the United States and in India. It

* *Engineering News*, Vol. 60, p. 212.

will be seen, therefore, that in the case of this reservoir all conditions are favorable for the retention of large quantities of silt.

The area of the water-shed tributary to the Zuni Reservoir has been quoted as 650 sq. miles. From this, however, should be deducted the area above the Ramah Dam and a considerable area of rolling country where the drainage flows into natural shallow tanks or basins. Unless there is a cloudburst, there is no overflow from these natural basins, and the precipitation rarely if ever runs into the Zuni River. It is thought that 500 sq. miles more closely represents the real area of the water-shed draining into the Zuni Reservoir.

There are no records of the rainfall in this drainage area, and a study of the run-off divided into periods, as given in Table 3, will show that the precipitation is very irregular. During the two years, January, 1912, to January, 1914, the average run-off was less than 7 200 acre-ft., while from January, 1914, to January, 1918, the average run-off exceeded 56 000 acre-ft. It is probable that the average annual rainfall of the water-shed is between 10 and 16 in., and until rainfall records are available on the water-shed, no relation between the rainfall and the run-off can be determined.

It is generally believed that the quantity of silt carried by any stream is largely in proportion to the magnitude of the floods, but, according to the records at Zuni, little relation is found between the magnitude of the flow and the silt carried. During the period from 1906 to 1910, with an average annual run-off of more than 14 000 acre-ft., the percentage of silt deposit was 3.2. In the next year and a half, with an average run-off of 16 420 acre-ft., the silt deposit was 5.4 per cent. During the next period of two years, with a minimum run-off amounting to a little more than 7 000 acre-ft. per year, the silt deposit was 7.3% of the total, while in the last period of four years, with an average annual run-off of more than 56 000 acre-ft., it was a little more than one-half of 1% (0.58%), and for the total period of 11½ years, the solids deposited from the run-off were 1.71 per cent.

In estimating the probable life of the reservoir, the percentage of silt in the run-off has been neglected, and the annual average quantity of silt actually deposited has been used.

In an article* by Herman Stabler, M. Am. Soc. C. E., and Mr. Horatio M. Parker, regarding the silt carried by the Kaw River, they

* *Engineering News*, Vol. 63, p. 644.

state that, in June, 1908, the river carried 41.4%, and in May, June, July, and August, 1908, 80.7% of the total for two years. From this they deduce: "The extraordinary influence of great floods, in erosion and denudation, is clearly shown." While this may be true of the flow of large rivers, it does not seem to be true in the case of the flashy streams of the Southwest, where the lesser volume of water in a year, coming in a few periods of run-off, seems to carry the greatest quantity of silt.

TABLE 3.—SHOWING RUN-OFF, IN ACRE-FEET, OF THE ZUNI RIVER, AT BLACKROCK, N. MEX.

Total run-off for 1906 and 1907, 38 000 acre-ft.
January to June, 1908, 2 200 acre-ft.
July to September, 1908, 2 900 acre-ft.
October, 1907, to June, 1908, 500 acre-ft.

Total run-off, 1906 to 1918, inclusive, 326 779 acre-ft.

It has occurred to the writer that the great difference in the quantity of silt carried by the water may be explained, to a certain extent, by the fact that during the periods of lesser run-off the ground in the water-shed and the stream bed are very dry and, consequently, easily eroded by the floods, and that during the periods of greater run-off, more evenly distributed, the ground and the stream channels are kept moist and, therefore, are not subject to as great erosion during the beginning of heavy precipitation and run-off.

A remedy is not easily suggested. The situation involves a serious fact, not a theory, and at a very early date it will be necessary to put into practice some method of getting rid of the silt. Otherwise, a

project built at a cost of more than $500 000, under which more than 3 500 acres are now being cultivated, and products valued at more than $68 000 were raised last year by the Indians, will have to be abandoned inside of 20 years. It will be necessary to raise the spillway elevation within a year or two, for the entire capacity of the reservoir to-day is only slightly in excess of one year's need for the present area of cultivated land.

Certain remedial measures have been suggested. One of these is to construct a set of small overflow dams in the stream above the reservoir. Even if these could be successfully constructed, and maintained at a reasonable cost, the silt accumulation of one year would fill a small one, and the ultimate filling of the main basin would be postponed only a short time.

It also has been suggested that much of the silt comes from the rapid cutting of the banks of the stream, and that rip-rapping these banks at the critical points would prevent further erosion and reduce the quantity of silt coming into the reservoir. The main stream is too long to make this feasible, and it has not been observed that the waters were any less heavily charged with silt at the head-waters of the feeder streams than in the main stream.

It also has been suggested that large sluices be installed at a low elevation, and the silt be gotten rid of in that manner; but observation in cases where dams have given way and the entire content of water run out through the opening, discloses that the quantity of silt sluiced out has been almost negligible.

The St. Johns Reservoir, in Arizona, the Austin Reservoir, and others, would indicate that a channel no wider than the opening, and extending back for a short distance, with almost vertical sides, would be the result.

The only plan that sounds at all feasible is that outlined roughly by the Consulting Engineer, J. H. Quinton, M. Am. Soc. C. E., when he was on the project some years ago.

This plan was to have a floating pipe line, connected with the lowest valve on the tower, now below the bottom of the reservoir. On a barge out in the lake, a cutter and nozzle were to be mounted, with a gasoline engine for power to operate the cutter and a small vacuum pump. With a flow started through this pipe line, no power would be required to continue such flow other than the operation of the vacuum pump

which would be placed at the highest point on the pipe line. What is really a suction dredge would thus be provided, and if all the water drawn from the reservoir was taken out in this manner, large quantities of silt could be removed.

Possible objections would be that in dry seasons there would not be sufficient water to waste, and all the water, heavily ladened with silt, would have to run into the canal, and, without a silt trap, it might fill up the two siphons in the canal. If it did not do this, much silt would be deposited in the canal and cause considerable expense and trouble for its removal.

It is thought that some means of combatting the silt will be evolved, but, with the rapid filling up of the reservoir, steps should be taken at once to find a solution of the problem.

DISCUSSION

ELWOOD MEAD,* M. AM. SOC. C. E. (by letter).—This paper deals with the most serious problem of water conservation in the arid Southwest. The author shows that the Zuni Reservoir which cost $500 000, has lost six-tenths of its capacity in 12½ years, that the reservoir near Carlsbad, N. Mex., has lost more than half its capacity in 15 years, and that, in a few years more, both these basins will be mud-flats of no value for irrigation. Mr. Mead.

The same menace confronts nearly every reservoir built in the channel of streams in the southern half of the arid region. The Rio Grande at times carries so much silt that it runs in waves, like the tailings away from a stamp-mill. In its channel, and in those of other sediment-laden streams, great reservoirs have been built, and millions of dollars have been or are being spent on irrigation channels, clearing, leveling, and draining lands, building houses, and planting orchards. The benefits to come from all this endeavor and expense depend on the water supply being permanent, on the storages being maintained to practically their full capacity. Every one knows that, unless some plan of desilting is devised and put into operation soon, this will not be the result, and that the life of all these storages will be comparatively brief.

These great undertakings are examples of the happy-go-lucky practice of acting first and thinking afterward; of refusing to see things that are disagreeable. The people of the Southwest wanted irrigation; they wanted the deserts made green, but they were not willing to wait until some feasible plan of desilting was worked out. The water was needed; the immediate results would be good, let the future and the people who would buy these farms, take care of themselves.
